

# Principles of Tissue Engineering

Third Edition

Edited by

**Robert Lanza**

**Robert Langer**

**Joseph Vacanti**

*On the cover:* Deborah Odum Hutchinson is an award winning and nationally published medical artist. After working seven years for the College of Medicine at Texas A&M University, she has been doing freelance art for 19 years. She is also known for her work in watercolors as a fine artist. Her work is a sensitive creation of the delicate anatomical aspects of the body as well as the artistic aspect of the figure in her final illustrations.

# CONTENTS IN BRIEF

Contributors	xix	<b>Part V. Biomaterials in Tissue Engineering</b>	<b>263</b>
Foreword	xxix	19. Micro-Scale Patterning of Cells and Their Environment	265
Preface	xxxj	20. Cell Interactions with Polymers	279
Preface to the Second Edition	xxxiii	21. Matrix Effects	297
Preface to the First Edition	xxxv	22. Polymer Scaffold Fabrication	309
<b>Introduction to Tissue Engineering</b>	<b>1</b>	23. Biodegradable Polymers	323
1. The History and Scope of Tissue Engineering	3	24. Micro- and Nanofabricated Scaffolds	341
2. The Challenge of Imitating Nature	7	25. Three-Dimensional Scaffolds	358
3. Moving into the Clinic	15	<b>Part VI. Transplantation of Engineered Cells and Tissues</b>	<b>375</b>
4. Future Perspectives	33	26. Tissue Engineering and Transplantation in the Fetus	377
<b>Part I. The Basis of Growth and Differentiation</b>	<b>51</b>	27. Immunomodulation	389
5. Molecular Biology of the Cell	53	28. Immunoisolation	399
6. Organization of Cells into Higher-Ordered Structures	67	29. Engineering Challenges in Immunobarrier Device Development	405
7. Dynamics of Cell-ECM Interactions	81	<b>Part VII. Stem Cells</b>	<b>419</b>
8. Matrix Molecules and Their Ligands	101	30. Embryonic Stem Cells	421
9. Morphogenesis and Tissue Engineering	117	31. Adult Epithelial Tissue Stem Cells	431
10. Gene Expression, Cell Determination, and Differentiation	129	32. Embryonic Stem Cells as a Cell Source for Tissue Engineering	445
<b>Part II. In Vitro Control of Tissue Development</b>	<b>135</b>	33. Postnatal Stem Cells	459
11. Engineering Functional Tissues	137	<b>Part VIII. Gene Therapy</b>	<b>469</b>
12. Principles of Tissue Culture and Bioreactor Design	155	34. Gene Therapy	471
13. Regulation of Cell Behavior by Extracellular Proteins	185	35. Gene Delivery into Cells and Tissues	493
14. Growth Factors	193	<b>Part IX. Breast</b>	<b>517</b>
15. Mechanochemical Control of Cell Fate Switching	207	36. Breast Reconstruction	519
<b>Part III. In Vivo Synthesis of Tissues and Organs</b>	<b>217</b>	<b>Part X. Cardiovascular System</b>	<b>535</b>
16. In Vivo Synthesis of Tissues and Organs	219	37. Progenitor Cells and Cardiac Homeostasis	537
<b>Part IV. Models for Tissue Engineering</b>	<b>239</b>	38. Cardiac Tissue Engineering	551
17. Models as Precursors for Prosthetic Devices	241	39. Blood Vessels	569
18. Quantitative Aspects	251	40. Heart Valves	585
		<b>Part XI. Endocrinology and Metabolism</b>	<b>603</b>
		41. Generation of Islets from Stem Cells	605
		42. Bioartificial Pancreas	619

## vi CONTENTS IN BRIEF

43. Engineering Pancreatic Beta-Cells	635	<b>Part XVII. Ophthalmic Applications</b>	<b>1009</b>
44. Thymus and Parathyroid Organogenesis	647	67. Stem Cells in the Eye	1011
<b>Part XII. Gastrointestinal System</b>	<b>663</b>	68. Corneal-Tissue Replacement	1025
45. Adult Stem Cells in Normal Gastrointestinal Function and Inflammatory Disease	665	69. Vision Enhancement Systems	1049
46. Alimentary Tract	681	<b>Part XVIII. Oral/Dental Applications</b>	<b>1065</b>
47. Liver Stem Cells	695	70. Biological Tooth Replacement and Repair	1067
48. Liver	707	71. Oral and Maxillofacial Surgery	1079
<b>Part XIII. Hematopoietic System</b>	<b>733</b>	72. Periodontal-Tissue Engineering	1095
49. Hematopoietic Stem Cells	735	<b>Part XIX. Respiratory System</b>	<b>1111</b>
50. Red Blood Cell Substitutes	749	73. Progenitor Cells in the Respiratory System	1113
51. Lymphoid Cells	759	74. Lungs	1125
<b>Part XIV. Kidney and Genitourinary System</b>	<b>785</b>	<b>Part XX. Skin</b>	<b>1135</b>
52. Stem Cells in Kidney Development and Regeneration	787	75. Cutaneous Stem Cells	1137
53. Renal Replacement Devices	801	76. Wound Repair	1149
54. Genitourinary System	811	77. Bioengineered Skin Constructs	1167
<b>Part XV. Musculoskeletal System</b>	<b>821</b>	<b>Part XXI. Clinical Experience</b>	<b>1187</b>
55. Mesenchymal Stem Cells	823	78. Current State of Clinical Application	1189
56. Bone Regeneration	845	79. Tissue-Engineered Skin Products	1201
57. Bone and Cartilage Reconstruction	861	80. Tissue-Engineered Cartilage Products	1215
58. Regeneration and Replacement of the Intervertebral Disc	877	81. Tissue-Engineered Bone Products	1225
59. Articular Cartilage Injury	897	82. Tissue-Engineered Cardiovascular Products	1237
60. Tendons and Ligaments	909	83. Tissue-Engineered Organs	1253
61. Mechanosensory Mechanisms in Bone	919	<b>Part XXII. Regulation and Ethics</b>	<b>1263</b>
62. Skeletal-Tissue Engineering	935	84. The Tissue-Engineering Industry	1265
<b>Part XVI. Nervous System</b>	<b>945</b>	85. The Regulatory Path From Concept to Market	1271
63. Neural Stem Cells	947	86. Ethical Issues	1281
64. Brain Implants	967	Epilogue	1289
65. Spinal Cord	977	Subject Index	1291
66. Protection and Repair of Audition	995		

# CONTENTS

Contributors	xix	III. The Cytoplasm	56
Foreword	xxix	IV. Growth and Death	58
Preface	xxx	V. Cytoskeleton	60
Preface to the Second Edition	xxxiii	VI. Cell Adhesion Molecules	61
Preface to the First Edition	xxxv	VII. Extracellular Matrix	62
		VIII. Culture Media	63

		X. Further Reading	65
<b>Introduction to Tissue Engineering</b>	<b>1</b>		
1. The History and Scope of Tissue Engineering <i>Joseph Vacanti and Charles A. Vacanti</i>	3	6. Organization of Cells into Higher-Ordered Structures <i>Jon D. Ahrstrom and Carol A. Erickson</i>	67
I. Introduction	3	I. Introduction	67
II. Scientific Challenges	4	II. Molecular Mechanisms of the EMT	68
III. Cells	4	III. The EMT Transcriptional Program	70
IV. Materials	5	IV. Molecular Control of the EMT	72
V. General Scientific Issues	5	V. Conclusion	76
VI. Social Challenges	6	VI. References	76
VII. References	6		
2. The Challenge of Imitating Nature <i>Robert M. Nerem</i>	7	7. The Dynamics of Cell-ECM Interactions <i>M. Petreanu and Manuela Martins-Green</i>	81
I. Introduction	7	I. Introduction	81
II. Cell Technology	8	II. Cell-ECM Interactions	84
III. Construct Technology	10	III. Signal Transduction Events During Cell-ECM Interactions	90
IV. Integration into the Living System	11	IV. Relevance for Tissue Engineering	93
V. Concluding Discussion	12	V. References	95
VI. Acknowledgments	13		
VII. References	13	8. Matrix Molecules and Their Ligands <i>Bjorn Helmo Olsen</i>	101
3. Moving into the Clinic <i>Alan J. Russell and Timothy Bertram</i>	15	I. Introduction	101
I. Introduction	15	II. Collagens — Major Constituents of ECM	102
II. History of Clinical Tissue Engineering	16	III. Elastic Fibers and Microfibrils	107
III. Strategies to Advance Toward the Clinic	20	IV. Other Multifunctional Proteins in ECM	107
IV. Bringing Technology Platforms to the Clinical Setting	26	V. Proteoglycans — Multifunctional Molecules in the Extracellular Matrix and on Cell Surfaces	111
V. Transition to Clinical Testing	28	VI. Conclusion	112
VI. Establishing a Regulatory Pathway	30	VII. References	112
VII. Conclusions	30		
VIII. Acknowledgments	30	9. Morphogenesis and Tissue Engineering <i>A. H. Rosoff</i>	117
IX. References	31	I. Introduction	117
4. Future Perspectives <i>Mark E. Furth and Anthony Atala</i>	33	II. Bone Morphogenetic Proteins (BMPs)	118
I. Clinical Need	33	III. Cartilage-Derived Morphogenetic Proteins (CDMPs)	121
II. Current State of the Field	33	IV. Pleiotropy and Thresholds	121
III. Current Challenges	34	V. BMPs Bind to Extracellular Matrix	122
IV. Future Directions	34	VI. BMP Receptors	122
V. Future Challenges	42	VII. Responding Stem Cells	123
VI. References	42	VIII. Morphogens and Gene Therapy	123
		IX. Biomimetic Biomaterials	124
<b>Part I. The Basis of Growth and Differentiation</b>	<b>51</b>	X. Tissue Engineering of Bones and Joints	124
5. Molecular Biology of the Cell <i>Jonathan Slack</i>	53	XI. Future Challenges	125
I. Introduction	53	XII. Acknowledgments	126
II. The Cell Nucleus	54	XIII. References	126

10. Gene Expression, Cell Determination, and Differentiation <i>William Nikovits, Jr., and Frank E. Stockdale</i>	129	III. Growth Factors and Cytokines Active as Early Mediators of the Inflammatory Process	195
I. Introduction	129	IV. Inflammatory Response Mediators Activate Transcription of Quiescent Genes	196
II. Determination and Differentiation	129	V. Biologic Properties of SIG (Chemokine) Family Members	197
III. MyoD and the bHLH Family of Developmental Regulatory Factors	131	VI. Regulation of <i>IE</i> Gene Expression by Glucocorticoids	197
IV. MEFs — Coregulators of Development	132	VII. Growth Factors and Accelerated Healing	197
V. Pax in Development	132	VIII. Role of Basic Fibroblast Growth Factor and Angiogenesis	199
VI. Conclusions	132	IX. Pleiotrophin Remodels Tumor Microenvironment and Stimulates Angiogenesis	200
VII. References	133	X. Other Roles of Growth Factors and Cytokines	201
<b>Part II. In Vitro Control of Tissue Development</b>	<b>135</b>	XI. Conclusions	201
11. Engineering Functional Tissues <i>Lisa E. Freed and Faridul Guilak</i>	137	XII. References	201
I. Introduction	137	15. Mechanochemical Control of Cell Fate Switching <i>Donald E. Ingber</i>	207
II. Key Concepts	138	I. Introduction	207
III. <i>In Vitro</i> Studies Aimed at Clinical Translation	139	II. Extracellular Matrix Structure and Function	207
IV. Representative <i>In Vitro</i> Culture Environments	139	III. Pattern Formation Through ECM Remodeling	209
V. Convective Mixing, Flow, and Mass Transfer	142	IV. Mechanochemical Switching Between Cell Fates	210
VI. Culture Duration and Mechanical Conditioning	145	V. Summary	213
VII. Conclusions	149	VI. The Future	213
VIII. Acknowledgments	150	VII. Acknowledgments	214
IX. References	150	VIII. References	214
12. Principles of Tissue Culture and Bioreactor Design <i>R. I. Freshney, B. Obradovic, W. Grayson, C. Cannizzaro, and Gordana Vunjak-Novakovic</i>	155	<b>Part III. In Vivo Synthesis of Tissues and Organs</b>	<b>217</b>
I. Introduction	155	16. <i>In Vivo</i> Synthesis of Tissues and Organs <i>Brendan A. Harley and Ioannis V. Yannas</i>	219
II. Basic Principles of Cell and Tissue Culture	155	I. Introduction	219
III. Principles of Bioreactor Design	164	II. Mammalian Response to Injury	220
IV. Summary	180	III. Methods to Treat Loss of Organ Function	221
V. Acknowledgments	180	IV. Active Extracellular Matrix Analogs	223
VI. References	180	V. Basic Parameters for <i>In Vivo</i> Regeneration Studies: Reproducible, Nonregenerative Wounds	227
13. Regulation of Cell Behavior by Extracellular Proteins <i>Amy D. Bradshaw and E. Helene Sage</i>	185	VI. Examples of <i>In Vivo</i> Organ Regeneration	228
I. Introduction	185	VII. Conclusions	235
II. Thrombospondin-1	185	VIII. Acknowledgments	236
III. Thrombospondin-2	187	IX. References	236
IV. Tenascin-C	187	<b>Part IV. Models for Tissue Engineering</b>	<b>239</b>
V. Osteopontin	188	17. Models as Precursors for Prosthetic Devices <i>Eugene Bell</i>	241
VI. SPARC	189	I. Introduction	241
VII. Conclusions	190	II. Pigmentation of the Living-Skin Equivalent (LSE) <i>In Vitro</i>	244
VIII. References	191		
14. Growth Factors <i>Thomas F. Deuel and Yunchao Cheng</i>	193		
I. Introduction	193		
II. Wound Healing	194		

III. The Living-Skin Equivalent as an Immunological Model	244	V. Conclusions	304
IV. The Living-Skin Equivalent as a Disease Model	244	VI. References	305
V. Wound-Healing Model	246		
VI. Vascular Models without Cells	247	22. Polymer Scaffold Fabrication	309
VII. Vascular Models with Cells Added	247	<i>Matthew B. Murphy and Antonios G. Mikos</i>	
VIII. Conclusions	248	I. Introduction	309
IX. References	248	II. Fiber Bonding	310
		III. Electrospinning	311
18. Quantitative Aspects	251	IV. Solvent Casting and Particulate Leaching	311
<i>Alan J. Grodzinsky, Roger D. Kamm, and Douglas A. Lauffenburger</i>		V. Melt Molding	312
I. Introduction	251	VI. Membrane Lamination	312
II. Molecular Interactions with Cells	251	VII. Extrusion	312
III. Molecular and Cell Transport Through Tissue	253	VIII. Freeze-Drying	313
IV. Cell and Tissue Mechanics	256	IX. Phase Separation	313
V. References	260	X. High-Internal-Phase Emulsion	313
		XI. Gas Foaming	313
		XII. Polymer/Ceramic Composite Fabrication	314
		XIII. Rapid Prototyping of Solid Free Forms	315
		XIV. Peptide Self-Assembly	316
		XV. <i>In Situ</i> Polymerization	316
		XVI. Conclusions	317
		XVII. Acknowledgments	317
		XVIII. References	320
<b>Part V. Biomaterials in Tissue Engineering</b>	<b>263</b>	23. Biodegradable Polymers	323
19. Micro-Scale Patterning of Cells and Their Environment	265	<i>James M. Pachence, Michael P. Bohrer, and Joachim Kohn</i>	
<i>Xingyu Jiang, Shuichi Takayama, Robert G. Chapman, Ravi S. Kane, and George M. Whitesides</i>		I. Introduction	323
I. Introduction	265	II. Biodegradable Polymer Selection Criteria	323
II. Soft Lithography	266	III. Biologically Derived Bioresorbables	324
III. Self-Assembled Monolayers (SAMs)	266	IV. Synthetic Polymers	327
IV. Microcontact Printing and Microfeatures Used in Cell Biology	267	V. Creating Materials for Tissue-Engineered Products	332
V. Microfluidic Patterning	272	VI. Conclusion	333
VI. Laminar Flow Patterning	272	VII. References	333
VII. Conclusion and Future Prospects	274		
VIII. Acknowledgments	275	24. Micro- and Nanofabricated Scaffolds	341
IX. References	275	<i>Christopher J. Bettinger, Jeffrey T. Bonstein, and Robert Langer</i>	
20. Cell Interactions with Polymers	279	I. Introduction	341
<i>W. Mark Saltzman and Themis R. Kyriakides</i>		II. Adaptation of Traditional Micro-Scale Techniques for Scaffold Fabrication	342
I. Introduction	279	III. Three-Dimensional Scaffolds with Micro-Scale Architecture	346
II. Methods for Characterizing Cell Interactions with Polymers	279	IV. Three-Dimensional Scaffold Assembly	348
III. Cell Interactions with Polymers	283	V. Microfabrication of Cell-Seeded Scaffolds	352
IV. Cell Interactions with Polymers in Suspension	289	VI. Summary and Future Direction	356
V. Cell Interactions with Three-Dimensional Polymer Scaffolds and Gels	291	VII. References	357
VI. Cell Interactions Unique to the <i>In Vivo</i> Setting	292		
VII. References	292	25. Three-Dimensional Scaffolds	359
21. Matrix Effects	297	<i>Ying Luo, George Engelmayr, Debra T. Augustine, Lino da Silva Ferreira, Jeffrey M. Karp, Rajiv Saigal, and Robert Langer</i>

## FOREWORD

Robert Langer

Since the mid-1980s, tissue engineering has moved from a concept to a very significant field. Already we are at the point where numerous tissues, such as skin, cartilage, bone, liver, blood vessels, and others, are in the clinic or even approved by regulatory authorities. Many other tissues are being studied. In addition, the advent of human embryonic stem cells has brought forth new sources of cells that may be useful in a variety of areas of tissue engineering.

This third edition of *Principles of Tissue Engineering* examines a variety of important areas. In the introductory section, an important overview on the history of tissue engineering and the movement of engineered tissues into the clinic is examined. This is followed by an analysis of important areas in cell growth and differentiation, including aspects of molecular biology, extracellular matrix interactions, cell morphogenesis, and gene expression and differentiation. Next, *in vitro* and *in vivo* control of tissue and organ development is examined. Important aspects of tissue culture and bioreactor design are covered, as are aspects of cell behavior and control by growth factors and cell mechanics. Models for tissue engineering are also examined. This includes mathematical models that can be used to predict important phenomena in tissue engineering and related medical devices. The involvement of biomaterials in tissue engineering is also addressed. Important aspects of polymers, extracellular matrix, materials processing, novel polymers such as biodegradable polymers as well as micro- and nano-fabricated scaffolds and three-dimensional scaffolds are discussed. Tissue and cell transplantation, including methods of immunoisolation, immunomodulation, and even transplantation in the fetus, are analyzed.

As mentioned earlier, stem cells have become an important part of tissue engineering. As such, important coverage of embryonic stem cells, adult stem cells, and postnatal stem cells is included. Gene therapy is another important area, and both general aspects of gene therapy as well as intracellular delivery of genes and drugs to cells and tissues are discussed. Various important engineered tissues, including breast-tissue engineering, tissues of the cardiovascular systems, such as myocardium, blood vessels, and heart valves, endocrine organs, such as the pancreas and the thymus, are discussed, as are tissues of the gastrointestinal system, such as liver and the alimentary tract. Important aspects of the hematopoietic system are analyzed, as is the engineering of the kidney and genitourinary system.

Much attention is devoted to the muscular skeletal system, including bone and cartilage regeneration and tendon and ligament placement. The nervous system is also discussed, including brain implants and the spinal cord. This is followed by a discussion of the eye, where corneal replacement and vision enhancement systems are examined. Oral and dental applications are also discussed, as are the respiratory system and skin. The concluding sections of the book cover clinical experience in such areas as cartilage, bone, skin, and cardiovascular systems as well as the bladder. Finally, regulatory and ethical considerations are examined.

In sum, the 86 chapters of this third edition of *Principles of Tissue Engineering* examine the important advances in the burgeoning field of tissue engineering. This volume will be very useful for scientists, engineers, and clinicians engaging in this important new area of science and medicine.

## PREFACE

The third edition of *Principles of Tissue Engineering* attempts to incorporate the latest advances in the biology and design of tissues and organs and simultaneously to connect the basic sciences — including new discoveries in the field of stem cells — with the potential application of tissue engineering to diseases affecting specific organ systems. While the third edition furnishes a much-needed update of the rapid progress that has been achieved in the field since the turn of the century, we have retained those facts and sections that, while not new, will assist students and general readers in understanding this exciting area of biology.

The third edition of *Principles* is divided into 22 parts plus an introductory section and an Epilogue. The organization remains largely unchanged from previous editions, combining the prerequisites for a general understanding of tissue growth and development, the tools and theoretical information needed to design tissues and organs, and a presentation by the world's experts on what is currently known about each specific organ system. As in previous editions, we have striven to create a comprehensive book that, on one hand, strikes a balance among the diversity of subjects that are related to tissue engineering, including biology, chemistry, materials science, and engineering, while emphasizing those research areas likely to be of clinical value in the future.

No topic in the field of tissue engineering is left uncovered, including basic biology/mechanisms, biomaterials, gene therapy, regulation and ethics, and the application of tissue engineering to the cardiovascular, hematopoietic, musculoskeletal, nervous, and other organ systems. While we cannot describe all of the new and updated material of the third edition, we can say that we have expanded and given added emphasis to stem cells, including adult and embryonic stem cells, and progenitor populations that may soon lead to new tissue-engineering therapies for heart disease, diabetes, and a wide variety of other diseases that afflict humanity. This up-to-date coverage of stem cell biology and other emerging technologies is complemented by a series of new chapters on recent clinical experience in applying tissue engineering. The result is a comprehensive book that we believe will be useful to students and experts alike.

*Robert Lanza*  
*Robert Langer*  
*Joseph Vacanti*

## PREFACE TO THE SECOND EDITION

The first edition of this textbook, published in 1997, was rapidly recognized as the comprehensive textbook of tissue engineering. This edition is intended to serve as a comprehensive text for the student at the graduate level or the research scientist/physician with a special interest in tissue engineering. It should also function as a reference text for researchers in many disciplines. It is intended to cover the history of tissue engineering and the basic principles involved, as well as to provide a comprehensive summary of the advances in tissue engineering in recent years and the state of the art as it exists today.

Although many reviews had been written on the subject and a few textbooks had been published, none had been as comprehensive in its defining of the field, description of the scientific principles and interrelated disciplines involved, and discussion of its applications and potential influence on industry and the field of medicine in the future as the first edition.

When one learns that a more recent edition of a textbook has been published, one has to wonder if the base of knowledge in that particular discipline has grown sufficiently to justify writing a revised textbook. In the case of tissue engineering, it is particularly conspicuous that developments in the field since the printing of the first edition have been tremendous. Even experts in the field would not have been able to predict the explosion in knowledge associated with this development. The variety of new polymers and materials now employed in the generation of engineered tissue has grown exponentially, as evidenced by data associated with specialized applications. More is learned about cell/biomaterials interactions on an almost daily basis. Since the printing of the last edition, recent work has demonstrated a tremendous potential for the use of stem cells in tissue engineering. While some groups are working with fetal stem cells, others believe that each specialized tissue contains progenitor cells or stem cells that are already somewhat committed to develop into various specialized cells of fully differentiated tissue.

Parallel to these developments, there has been a tremendous “buy in” concerning the concepts of tissue engineering not only by private industry but also by practicing physicians in many disciplines. This growing interest has resulted in expansion of the scope of tissue engineering well beyond what could have been predicted five years ago and has helped specific applications in tissue engineering to advance to human trials.

The chapters presented in this text represent the results of the coordinated research efforts of several hundred scientific investigators internationally. The development of this text in a sense parallels the development of the field as a whole and is a true reflection of the scientific cooperation expressed as this field evolves.

*Robert Lanza  
Robert Langer  
Joseph Vacanti*

## PREFACE TO THE FIRST EDITION

Although individual papers on various aspects of tissue engineering abound, no previous work has satisfactorily integrated this new interdisciplinary subject area. *Principles of Tissue Engineering* combines in one volume the prerequisites for a general understanding of tissue growth and development, the tools and theoretical information needed to design tissues and organs, as well as a presentation of applications of tissue engineering to diseases affecting specific organ system. We have striven to create a comprehensive book that, on the one hand, strikes a balance among the diversity of subjects that are related to tissue engineering, including biology, chemistry, materials science, engineering, immunology, and transplantation among others, while, on the other hand, emphasizing those research areas that are likely to be of most value to medicine in the future.

The depth and breadth of opportunity that tissue engineering provides for medicine is extraordinary. In the United States alone, it has been estimated that nearly half-a-trillion dollars are spent each year to care for patients who suffer either tissue loss or end-stage organ failure. Over four million patients suffer from burns, pressure sores, and skin ulcers, over twelve million patients suffer from diabetes, and over two million patients suffer from defective or missing supportive structures such as long bones, cartilage, connective tissue, and intervertebral discs. Other potential applications of tissue engineering include the replacement of worn and poorly functioning tissues as exemplified by aged muscle or cornea; replacement of small caliber arteries, veins, coronary, and peripheral stents; replacement of the bladder, ureter, and fallopian tube; and restoration of cells to produce necessary enzymes, hormones, and other bioactive secretory products.

*Principles of Tissue Engineering* is intended not only as a text for biomedical engineering students and students in cell biology, biotechnology, and medical courses at advanced undergraduate and graduate levels, but also as a reference tool for research and clinical laboratories. The expertise required to generate this text far exceeded that of its editors. It represents the combined intellect of more than eighty scholars and clinicians whose pioneering work has been instrumental to ushering in this fascinating and important field. We believe that their knowledge and experience have added indispensable depth and authority to the material presented in this book and that in the presentation, they have succeeded in defining and capturing the sense of excitement, understanding, and anticipation that has followed from the emergence of this new field, tissue engineering.

### I. INTRODUCTION

The dream is as old as humankind. Injury, disease, and congenital malformation have always been part of the human experience. If only damaged bodies could be restored, life could go on for loved ones as though tragedy had not intervened. In recorded history, this possibility first was manifested through myth and magic, as in the Greek legend of Prometheus and eternal liver regeneration. Then legend produced miracles, as in the creation of Eve in Genesis or the miraculous transplantation of a limb by the saints Cosmos and Damien. With the introduction of the scientific method came new understanding of the natural world. The methodical unraveling of the secrets of biology was coupled with the scientific understanding of disease and trauma. Artificial or prosthetic materials for replacing limbs, teeth, and other tissues resulted in the partial restoration of lost function. Also, the concept of using one tissue as a replacement for another was developed. In the 16th century, Tagliacozzi of Bologna, Italy, reported in his work *Decusorum Chirurgia per Insitionem* a description of a nose replacement that he constructed from a forearm flap. With the 19th-century scientific understanding of the germ theory of disease and the introduction of sterile technique, modern surgery emerged. The advent of anesthesia by

the mid-19th century enabled the rapid evolution of many surgical techniques. With patients anesthetized, innovative and courageous surgeons could save lives by examining and treating internal areas of the body: the thorax, the abdomen, the brain, and the heart. Initially the surgical techniques were primarily extirpative, for example, removal of tumors, bypass of the bowel in the case of intestinal obstruction, and repair of life-threatening injuries. Maintenance of life without regard to the crippling effects of tissue loss or the psychosocial impact of disfigurement, however, was not an acceptable end goal. Techniques that resulted in the restoration of function through structural replacement became integral to the advancement of human therapy.

Now whole fields of reconstructive surgery have emerged to improve the quality of life by replacing missing function through rebuilding body structures. In our current era, modern techniques of transplanting tissue and organs from one individual into another have been revolutionary and lifesaving. The molecular and cellular events of the immune response have been elucidated sufficiently to suppress the response in the clinical setting of transplantation and to produce prolonged graft survival and function in patients. In a sense, transplantation can be viewed as the

most extreme form of reconstructive surgery, transferring tissue from one individual into another.

As with any successful undertaking, new problems have emerged. Techniques using implantable foreign body materials have produced dislodgment, infection at the foreign body/tissue interface, fracture, and migration over time. Techniques moving tissue from one position to another have produced biologic changes because of the abnormal interaction of the tissue at its new location. For example, diverting urine into the colon can produce fatal colon cancers 20–30 years later. Making esophageal tubes from the skin can result in skin tumors 30 years later. Using intestine for urinary tract replacement can result in severe scarring and obstruction over time.

Transplantation from one individual into another, although very successful, has severe constraints. The major problem is accessing enough tissue and organs for all of the patients who need them. Currently, 92,587 people are on transplant waiting lists in the United States, and many will die waiting for available organs. Also, problems with the immune system produce chronic rejection and destruction over time. Creating an imbalance of immune surveillance from immunosuppression can cause new tumor formation. The constraints have produced a need for new solutions to provide needed tissue.

It is within this context that the field of tissue engineering has emerged. In essence, new and functional living tissue is fabricated using living cells, which are usually associated, in one way or another, with a matrix or scaffolding to guide tissue development. New sources of cells, including many types of stem cells, have been identified in the past several years, igniting new interest in the field. In fact, the emergence of stem cell biology has led to a new term, *regenerative medicine*. Scaffolds can be natural, man-made, or a composite of both. Living cells can migrate into the implant after implantation or can be associated with the matrix in cell culture before implantation. Such cells can be isolated as fully differentiated cells of the tissue they are hoped to recreate, or they can be manipulated to produce the desired function when isolated from other tissues or stem cell sources. Conceptually, the application of this new discipline to human health care can be thought of as a refinement of previously defined principles of medicine. The physician has historically treated certain disease processes by supporting nutrition, minimizing hostile factors, and optimizing the environment so that the body can heal itself. In the field of tissue engineering, the same thing is accomplished on a cellular level. The harmful tissue is eliminated; the cells necessary for repair are then introduced in a configuration optimizing survival of the cells in an environment that will permit the body to heal itself. Tissue engineering offers an advantage over cell transplantation alone in that organized three-dimensional functional tissue is designed and developed. This chapter summarizes some of the challenges that must be resolved before tissue engineering can become part of the therapeutic

armamentarium of physicians and surgeons. Broadly speaking, the challenges are scientific and social.

## II. SCIENTIFIC CHALLENGES

As a field, tissue engineering has been defined only since the mid-1980s. As in any new undertaking, its roots are firmly implanted in what went before. Any discussion of when the field began is inherently fuzzy. Much still needs to be learned and developed to provide a firm scientific basis for therapeutic application. To date, much of the progress in this field has been related to the development of model systems, which have suggested a variety of approaches. Also, certain principles of cell biology and tissue development have been delineated. The field can draw heavily on the explosion of new knowledge from several interrelated, well-established disciplines and in turn may promote the coalescence of relatively new, related fields to achieve their potential. The rate of new understanding of complex living systems has been explosive since the 1970s. Tissue engineering can draw on the knowledge gained in the fields of cell and stem cell biology, biochemistry, and molecular biology and apply it to the engineering of new tissues. Likewise, advances in materials science, chemical engineering, and bioengineering allow the rational application of engineering principles to living systems. Yet another branch of related knowledge is the area of human therapy as applied by surgeons and physicians. In addition, the fields of genetic engineering, cloning, and stem cell biology may ultimately develop hand in hand with the field of tissue engineering in the treatment of human disease, each discipline depending on developments in the others.

We are in the midst of a biologic renaissance. Interactions of the various scientific disciplines can elucidate not only the potential direction of each field of study, but also the right questions to address. The scientific challenge in tissue engineering lies both in understanding cells and their mass transfer requirements and the fabrication of materials to provide scaffolding and templates.

## III. CELLS

If we postulate that living cells are required to fabricate new tissue substitutes, much needs to be learned with regard to their behavior in two normal circumstances: normal development in morphogenesis and normal wound healing. In both of these circumstances, cells create or recreate functional structures using preprogrammed information and signaling. Some approaches to tissue engineering rely on guided regeneration of tissue using materials that serve as templates for ingrowth of host cells and tissue. Other approaches rely on cells that have been implanted as part of an engineered device. As we gain understanding of normal developmental and wound-healing gene programs and cell behavior, we can use them to our advantage in the rational design of living tissues.

Acquiring cells for creation of body structures is a major challenge, the solution of which continues to evolve. The ultimate goal in this regard — the large-scale fabrication of structures — may be to create large cell banks composed of universal cells that would be immunologically transparent to an individual. These universal cells could be differentiated cell types that could be accepted by an individual or could be stem cell reservoirs, which could respond to signals to differentiate into differing lineages for specific structural applications. Much is already known about stem cells and cell lineages in the bone marrow and blood. Studies suggest that progenitor cells for many differentiated tissues exist within the marrow and blood and may very well be ubiquitous. Our knowledge of the existence and behavior of such cells in various mesenchymal tissues (muscle, bone, and cartilage), endodermally derived tissues (intestine and liver), or ectodermally derived tissues (nerves, pancreas, and skin) expands on a daily basis. A new area of stem cell biology involving embryonic stem cells holds promise for tissue engineering. The calling to the scientific community is to understand the principles of stem and progenitor cell biology and then to apply that understanding to tissue engineering. The development of immunologically inert universal cells may come from advances in genetic manipulation as well as stem cell biology.

As intermediate steps, tissue can be harvested as allograft, autograft, or xenograft. The tissues can then be dissociated and placed into cell culture, where proliferation of cells can be initiated. After expansion to the appropriate cell number, the cells can then be transferred to templates, where further remodeling can occur. Which of these strategies are practical and possibly applicable in humans remains to be explored.

Large masses of cells for tissue engineering need to be kept alive, not only *in vitro* but also *in vivo*. The design of systems to accomplish this, including *in vitro* flow bioreactors and *in vivo* strategies for maintenance of cell mass, presents an enormous challenge, in which significant advances have been made. The fundamental biophysical constraint of mass transfer of living tissue needs to be understood and dealt with on an individual basis as we move toward human application.

#### IV. MATERIALS

There are so many potential applications to tissue engineering that the overall scale of the undertaking is enormous. The field is ripe for expansion and requires training of a generation of materials scientists and chemical engineers.

The optimal chemical and physical configurations of new biomaterials as they interact with living cells to produce tissue-engineered constructs are under study by many research groups. These biomaterials can be permanent or biodegradable. They can be naturally occurring materials, synthetic materials, or hybrid materials. They need to be

developed to be compatible with living systems or with living cells *in vitro* and *in vivo*. Their interface with the cells and the implant site must be clearly understood so that the interface can be optimized. Their design characteristics are major challenges for the field and should be considered at a molecular chemical level. Systems can be closed, semipermeable, or open. Each design should factor into the specific replacement therapy considered. Design of biomaterials can also incorporate the biologic signaling that the materials may offer. Examples include release of growth and differentiation factors, design of specific receptors and anchorage sites, and three-dimensional site specificity using computer-assisted design and manufacture techniques. New nanotechnologies have been incorporated to design systems of extreme precision. Combining computational models with nanofabrication can produce microfluidic circulations to nourish and oxygenate new tissues.

#### V. GENERAL SCIENTIFIC ISSUES

As new scientific knowledge is gained, many conceptual issues need to be addressed. Related to mass transfer is the fundamental problem associated with nourishing tissue of large mass as opposed to tissue with a relatively high ratio of surface area to mass. Also, functional tissue equivalents necessitate the creation of composites containing different cell types. For example, all tubes in the body are laminated tubes composed of a vascularized mesodermal element, such as smooth muscle, cartilage, or fibrous tissue. The inner lining of the tube, however, is specific to the organ system. Urinary tubes have a stratified transitional epithelium. The trachea has a pseudostratified columnar epithelium. The esophagus has an epithelium that changes along the gradient from mouth to stomach. The intestine has an enormous, convoluted surface area of columnar epithelial cells that migrate from a crypt to the tip of the villus. The colonic epithelium is, again, different for the purposes of water absorption and storage.

Even the well-developed manufacture of tissue-engineered skin used only the cellular elements of the dermis for a long period of time. Attention is now focusing on creating new skin consisting of both the dermis and its associated fibroblasts as well as the epithelial layer, consisting of keratinocytes. Obviously, this is a significant advance. But for truly “normal” skin to be engineered, all of the cellular elements should be contained so that the specialized appendages can be generated as well. These “simple” composites will indeed prove to be quite complex and require intricate designs. Thicker structures with relatively high ratios of surface area to mass, such as liver, kidney, heart, breast, and the central nervous system, will offer engineering challenges.

Currently, studies for developing and designing materials in three-dimensional space are being developed utilizing both naturally occurring and synthetic molecules. The applications of computer-assisted design and manufacture

techniques to the design of these matrices are critically important. Transformation of digital information obtained from magnetic resonance scanning or computerized tomography scanning can then be developed to provide appropriate templates. Some tissues can be designed as universal tissues that will be suitable for any individual, or they may be custom-developed tissues specific to one patient. An important area for future study is the entire field of neural regeneration, neural ingrowth, and neural function toward end organ tissues such as skeletal or smooth muscle. Putting aside the complex architectural structure of these tissues, the cells contained in them have a very high metabolic requirement. As such, it is exceedingly difficult to isolate a large number of viable cells. An alternate approach may be the use of less mature progenitor cells, or stem cells, which not only would have a higher rate of survival as a result of their lower metabolic demand but also would be more able to survive the insult and hypoxic environment of transplantation. As stem cells develop and require more oxygen, their differentiation may stimulate the development of a vascular complex to nourish them. The understanding of and solutions to these problems are fundamentally important to the success of any replacement tissue that needs ongoing neural interaction for maintenance and function.

It has been shown that some tissues can be driven to completion *in vitro* in bioreactors. However, optimal incubation times will vary from tissue to tissue. Even so, the new tissue will require an intact blood supply at the time of implantation for successful engraftment and function.

Finally, all of these characteristics need to be understood in the fourth dimension, time. If tissues are implanted in a growing individual, will the tissues grow at the same rate? Will cells taken from an older individual perform as young cells in their new “optimal” environment? How will the biochemical characteristics change over time after implantation? Can the strength of structural support tissues such as bone, cartilage, and ligaments be improved in a

bioreactor in which force vectors can be applied? When is the optimal timing of this transformation? When does tissue strength take over the biochemical characteristics as the material degrades?

## VI. SOCIAL CHALLENGES

If tissue engineering is to play an important role in human therapy, in addition to scientific issues, fundamental issues that are economic, social, and ethical in nature will arise. Something as simple as a new vocabulary will need to be developed and uniformly applied. A universal problem is funding. Can philanthropic dollars be accessed for the purpose of potential new human therapies? Will industry recognize the potential for commercialization and invest heavily? If this occurs, will the focus be changed from that of a purely academic endeavor? What role will governmental agencies play as the field develops? How will the field be regulated to ensure its safety and efficacy prior to human application? Is the new tissue to be considered transplanted tissue and, therefore, not be subject to regulation, or is it a pharmaceutical that must be subjected to the closest scrutiny by regulatory agencies? If lifesaving, should the track be accelerated toward human trials?

There are legal ramifications of this emerging technology as new knowledge is gained. What becomes proprietary through patents? Who owns the cells that will be sourced to provide the living part of the tissue fabrication?

In summary, one can see from this brief overview that the challenges in the field of tissue engineering remain significant. All can be encouraged by the progress that has been made in the past few years, but much discovery lies ahead. Ultimate success will rely on the dedication, creativity, and enthusiasm of those who have chosen to work in this exciting but still unproved field. Quoting from the epilogue of the previous edition: “At any given instant in time, humanity has never known so much about the physical world and will never again know so little.”

### I. INTRODUCTION

Tissue engineering, through the imitation of nature, has the potential to confront the transplantation crisis caused by the shortage of donor tissues and organs and also to address other important, but yet unmet, patient needs. If we are to be successful in this, a number of challenges need to be faced. In the area of cell technology, these include cell sourcing, the manipulation of cell function, and the effective use of stem cell technology. Next are those issues that are part of what is called here *construct technology*. These include the design and engineering of tissuelike constructs and/or delivery vehicles and the manufacturing technology required to provide off-the-shelf availability to the clinician. Finally, there are those issues associated with the integration of cells or a construct into the living system, where the most critical issue may be the engineering of immune acceptance. Only if we can meet the challenges presented by these issues and only if we can ultimately address the tissue engineering of the most vital of organs will it be possible to achieve success in confronting the crisis in transplantation.

An underlying premise of this is that the utilization of the natural biology of the system will allow for greater success in developing therapeutic strategies aimed at the replacement, maintenance, and/or repair of tissue and organ function. Another way of saying this is that, just maybe, the great creator, in whatever form one believes he

or she exists, knows something that we mere mortals do not, and if we can only tap into a small part of this knowledge base, if we can only imitate nature in some small way, then we will be able to achieve greater success in our efforts to address patient needs in this area. It is this challenge of imitating nature that has been accepted by those who are providing leadership to this new area of technology called *tissue engineering* (Langer and Vacanti, 1993; Nerem and Sambanis, 1995). To imitate nature requires that we first understand the basic biology of the tissues and organs of interest, including developmental biology; with this we then can develop methods for the control of these biologic processes; and based on the ability to control, we finally can develop strategies either for the engineering of living tissue substitutes or for the fostering of tissue repair or regeneration.

The initial successes have been for the most part substitutes for skin, a relatively simple tissue, at least by comparison with most other targets of opportunity. In the long term, however, tissue engineering has the potential for creating vital organs, such as the kidney, the liver, and the pancreas. Some even believe it will be possible to tissue engineer an entire heart. In addressing the repair, replacement, and/or regeneration of such vital organs, tissue engineering has the potential literally to confront the transplantation crisis, i.e., the shortage of donor tissues and organs available for transplantation. It also has the potential

to develop strategies for the regeneration of nerves, another important and unmet patient need.

Although research in what we now call tissue engineering started more than a quarter of a century ago, the term *tissue engineering* was not coined until 1987, when Professor Y. C. Fung, from the University of California, San Diego, suggested this name at a National Science Foundation meeting. This led to the first meeting called “tissue engineering,” held in early 1988 at Lake Tahoe, California (Skalak and Fox, 1988). More recently the term *regenerative medicine* has come into use. For some this is a code word for stem cell technology, while for others regenerative medicine is the broader term, with tissue engineering representing only replacement, not repair or regeneration. Still others use the terms *tissue engineering* and *regenerative medicine* interchangeably. What is important is that it is a more biologic approach that has the potential to lead to new patient therapies and treatments, where in some cases none is currently available.

It should be noted that the concept of a more biologic approach dates back to 1938 (Carrel and Lindbergh, 1938). Since then there has been a large expansion in research efforts in this field and a considerable recognition of the enormous potential that exists. With this hope, there also has been a lot of hype; however, the future long term remains bright (Nerem, 2006). As the technology has become further developed, an industry has begun to emerge. This industry is still very much a fledgling one, with only a few companies possessing product income streams (Ahsan and Nerem, 2005). A study based on 2002 data documents a total of 89 companies active in the field, with \$500 million annually in industrial research and development taking place (Lysaght and Hazlehurst, 2004). Although this study will soon be updated, based on the 2002 data, 80% of the new firms were in the stem cell area and 40% were located outside of the United States.

Tissue engineering is literally at the interface of the traditional medical implant industry and the biological revolution (Galletti *et al.*, 1995). By harnessing the advances of this revolution, we can create an entirely new generation of tissue and organ implants as well as strategies for repair and regeneration. Already we are seeing increased investments in this field by the large medical device companies. A part of this is a convergence of biologics and devices, which is recognized by the medical implant industry. It is from this that the short-term successes in tissue engineering will come; however, long term it is the potential for a literal revolution in medicine and in the medical device/implant industry that must be realized.

This revolution will only occur, however, if we successfully meet the challenge of imitating nature. Thus, in the remainder of this chapter the critical issues involved in this are addressed. This is done by first discussing those issues associated with cell technology, i.e., issues important in cell sourcing and in the achievement of the functional charac-

teristics required of the cells to be employed. Next to be discussed are those issues associated with construct technology. These include the organization of cells into a three-dimensional architecture that functionally mimics tissue, the development of vehicles for the delivery of genes, cells, and proteins, and the technologies required to manufacture such products and provide them off the shelf to the clinician. Finally, issues involved in the integration of a living cell construct into, or the fostering of remodeling within, the living system is discussed. These range from the use of appropriate animal models to the issues of biocompatibility and immune acceptance. Success in tissue engineering will only be achieved if issues at these three different levels, i.e., cell technology, construct technology, and the technology for integration into the living system, can be addressed.

II. CELL TECHNOLOGY

The starting point for any attempt to engineer a tissue or organ substitute is a consideration of the cells to be employed. Not only will one need to have a supply of sufficient quantity and one that can be ensured to be free of pathogens and contamination of any type whatsoever, but one will need to decide whether the source to be employed is to be autologous, allogeneic, or xenogeneic. As indicated in Table 2.1, each of these has both advantages and disadvantages; however, it should be noted that one important consideration for any product or treatment strategy is its off-the-shelf availability. This is obviously required for surgeries that must be carried out on short notice. However, even when the time for surgery is elective, it is only with off-the-shelf availability that the product and strategy will be used for the wide variety of patients who are in need and who are being treated throughout the entire health care system, including those in community hospitals.

With regard to the use of autologous cells, there are a number of potential sources. These include both differenti-

Table 2.1. Cell source	
Type	Comments
Autologous	Patient’s own cells; immune acceptable, but does not lend itself to off-the-shelf availability unless recruited from the host
Allogeneic	Cells from other human sources; lends itself to off-the-shelf availability, but may require engineering immune acceptance
Xenogeneic	From different species; not only requires engineering immune acceptance, but must be concerned with animal virus transmission

ated cells and adult stem/progenitor cells. It is only, however, if we can recruit the host's own cells, e.g., to an acellular implant, that we can have off-the-shelf availability, and it is only by moving to off-the-shelf availability for the clinician that routine use becomes possible.

The skin substitutes developed by Organogenesis (Canton, MA) and Advanced Tissue Sciences (La Jolla, CA) represented the first living-cell, tissue-engineered products, and these in fact use allogeneic cells. The Organogenesis product, Apligraf™, is a bilayer model of skin involving fibroblasts and keratinocytes that are obtained from donated human foreskin (Parenteau, 1999). Apligraf™ is approved by the Food and Drug Administration (FDA); however, the first tissue-engineered products approved by the FDA were acellular. These included Integra™, based on a polymeric template approach (Yannas *et al.*, 1982), and the Advanced Tissue Sciences product, TransCyte™. Approved initially for third-degree burns, TransCyte™ is made by seeding dermal fibroblasts in a polymeric scaffold; however, once cryopreserved it becomes a nonliving wound covering. Advanced Tissue Sciences also has a living-cell product, called Dermagraft™. It is a dermis model, also with dermal fibroblasts obtained from donated human foreskin (Naughton, 1999). Even though the cells employed by both Organogenesis and Advanced Tissue Sciences are allogeneic, immune acceptance did not have to be engineered because both the fibroblast and the keratinocyte do not constitutively express major histocompatibility complex (MHC) II antigens.

The next generation of tissue-engineered products will involve other cell types, and the immune acceptance of allogeneic cells will be a critical issue in many cases. As an example, consider a blood vessel substitute that employs both endothelial cells and smooth muscle cells. Although there is some unpublished data that suggest allogeneic smooth muscle cells may be immune acceptable, allogeneic endothelial cells certainly would not be. Thus, for the latter, one either uses autologous cells or else engineers the immune acceptance of allogeneic cells, as is discussed in a later section. Undoubtedly the first human clinical trials will be done using autologous endothelial cells; however, it appears that the use of such cells would severely limit the availability of a blood vessel substitute, unless the host's own endothelial cells are recruited.

Once one has selected the cell type(s) to be employed, then the next issue relates to the manipulation of the functional characteristics of a cell so as to achieve the behavior desired. This can be done either by (1) manipulating a cell's microenvironment, e.g., its matrix, the mechanical stresses to which it is exposed, or its biochemical environment, or by (2) manipulating a cell's genetic program. With regard to the latter, the manipulation of a cell's genetic program could be used as an ally to tissue engineering in a variety of ways. A partial list of possibilities includes the alteration of matrix synthesis; inhibition of the immune response; enhance-

ment of nonthrombogenicity, e.g., through increased synthesis of antithrombotic agents; engineering the secretion of specific biologically active molecules, e.g., a specific insulin secretion rate in response to a specific glucose concentration; and the alteration of cell proliferation.

Much of the foregoing is in the context of creating a cell-seeded construct that can be implanted as a tissue or organ substitute; however, the fostering of the repair or remodeling of tissue also represents tissue engineering as defined here. Here a critical issue is how to deliver the necessary biologic cues in a spatially and temporally controlled fashion so as to achieve a "healing" environment. In the repair and/or regeneration of tissue, the use of genetic engineering might take a form that is more what we would call *gene therapy*. An example of this would be the introduction of growth factors to foster the repair of bone defects. In using a gene therapy approach to tissue engineering it should be recognized that in many cases only a transient expression will be required. Because of this, the use of gene therapy as a strategy in tissue engineering may become viable prior to its employment in treating genetically related diseases.

Returning to the issue of cell selection, there is considerable interest in the use of stem cells as a primary source for cell-based therapies, ones ranging from replacement to repair and/or regeneration. This interest includes both adult stem cells and progenitor cells as well as embryonic stem cells (Ahsan and Nerem, in press; Vats *et al.*, 2005). With regard to the latter, the excitement about stem cells reached a new height in the late 1990s with articles reporting the isolation of the first lines of human embryonic stem cells (Thomson *et al.*, 1998; Solter and Gearhart, 1999; Vogel, 1999). Since then considerable progress has been made; however, the hype continues to outpace the progress. This reached an unfortunate crescendo in the latter part of 2005 with the revelation that the major advances reported by the Korean scientist Woo Suk Hwang were based on the fabrication of results (Normile and Vogel, 2005; Normile *et al.*, 2005, 2006). This was compounded by ethical issues and by the inclusion of Dr. Gerald Schatten from the University of Pittsburgh as a senior author (Guterman, 2006). Korea must be credited with launching a full investigation that led to Dr. Hwang's losing his position. The University of Pittsburgh also conducted an investigation and found Dr. Schatten guilty of "research misbehavior," a term not fully understood by the scientific community (Holden, 2006). The unfortunate thing is that this all happened at a time of considerable ethical and political controversy surrounding human embryonic stem cell research. From this we must all learn (Cho *et al.*, 2006), and, in spite of this setback in the public arena, research in the human embryonic stem cell area continues to hold considerable promise for the future.

There is in fact a variety of different stem cells, and several comprehensive reviews of a general nature have recently appeared (Vats *et al.*, 2005; Ahsan and Nerem, in

press). It is the adult stem cells and progenitor cells that are being and will be used first clinically; however, long term there is considerable interest in embryonic stem cells. These cells are pluripotent, i.e., capable of differentiating into many cell types, even totipotent, i.e., capable of developing into all cell types. Although we are quite a long way from being able to use embryonic stem cells, a number of companies are working with stem cells in the context of tissue engineering and regenerative medicine. It needs to be recognized, however, that immunogenicity issues may be associated with the use of embryonic stem cells. Furthermore, different embryonic stem cell lines, even when in a totally undifferentiated state, can be significantly different. This is illustrated by the results of Rao *et al.* (2004) in a comparison of the transcriptional profile of two different embryonic stem cell lines. This difference should not be considered surprising, since the lines were derived from different embryos and undoubtedly cultured under different conditions.

To take full advantage of stem cell technology, however, it will be necessary to understand more fully how a stem cell differentiates into a tissue-specific cell. This requires knowledge not just about the molecular pathways of differentiation, but, even more importantly, about the identification of the combination of signals leading to a stem cell's becoming a specific type of differentiated tissue cell. As an example, with the recognized differences between large-vessel endothelial cells and valvular endothelial cells (Butcher *et al.*, 2004), what are the signals that will drive the differentiation toward one type of endothelial cell versus the other? Only with this type of knowledge will we be able to realize the full potential of stem cells. In addition, however, we will need to develop the technologies necessary to expand a cell population to the number necessary for clinical application, to do this in a controlled, reproducible manner, and to deliver cells at the right place and at the time required.

### III. CONSTRUCT TECHNOLOGY

With the selection of a source of cells, the next challenge in imitating nature is to develop an organized three-dimensional architecture (with functional characteristics such that a specific tissue is mimicked) and/or a delivery vehicle for the cells. In this it is important to recognize the importance of a cell's microenvironment in determining its function. *In vivo* a cell's function is orchestrated by a symphony of signals. This symphony includes soluble molecules, the mechanical environment, i.e., physical forces, to which the cell is exposed, and the extracellular matrix. These are all part of the symphony. And if we want the end result to replicate the characteristics of native tissue, attention must be given to each of these components of a cell's microenvironment.

The design and engineering of a tissuelike substitute are challenges in their own right. If the approach is to seed cells into a scaffold, then a basic issue is the type of scaffold that

will allow the cells to make their own matrix. There are, of course, many possible approaches. One of these is a cell-seeded polymeric scaffold, an approach pioneered by Langer and his collaborators (Langer and Vacanti, 1993; Cima *et al.*, 1991). This is the technology that was used by Advanced Tissue Sciences, and many consider this the classic tissue-engineering approach. There are other approaches, however, with one of these being a cell-seeded collagen gel. This approach was pioneered by Bell in the late 1970s and early 1980s (Bell *et al.*, 1979; Weinberg and Bell, 1986), and this is used by Organogenesis in their skin substitute, Apligraf™.

A rather intriguing approach is that of Auger and his group in Quebec, Canada (Auger *et al.*, 1995; Heureux *et al.*, 1998). Auger refers to this as *cell self-assembly*, and it involves a layer of cells secreting their own matrix, which over a period of time becomes a sheet. Originally developed as part of the research on skin substitutes by Auger's group, it has been extended to other applications. For example, the blood vessel substitute developed in Quebec involves rolling up one of these cell self-assembled sheets into a tube. One can in fact make tubes of multiple layers so as to mimic the architecture of a normal blood vessel.

An equally intriguing approach is that pioneered by the Campbells in Australia and their collaborators (Chue *et al.*, 2004). In this they literally use the peritoneal cavity as an *in vivo* bioreactor to grow a blood vessel substitute. The concept is that a free-floating body in the peritoneal cavity initiates an inflammatory response and becomes encapsulated with cells. This is an autologous-cell approach, and it is also one where the cells make their own matrix.

Any discussion of different approaches to the creation of a three-dimensional, functional tissue equivalent would be remiss if acellular approaches were not included. Although in tissue engineering the end result should include functional cells, there are those who are employing a strategy whereby the implant is without cells, i.e., acellular, and the cells are then recruited from the recipient or host. A number of laboratories and companies are developing this approach. Examples include the products Integra™ and TransCyte™, already noted, and the development of SIS, i.e., small intestine submucosa (Badylak *et al.*, 1999; Lindberg and Badylak, 2001). One result of this approach, in effect, is to bypass the cell-sourcing issue and replace this with the issue of cell recruitment, i.e., the recruiting of cells from the host in order to populate the construct. Because these are the patient's own cells, there is no need for any engineering of immune acceptance.

Whatever is done, an objective in imitating nature must be to create a healing environment, one that will foster remodeling and ultimately repair. To do this requires delivering the appropriate, necessary cues in a controlled spatial and temporal fashion. This is needed whether the goal is replacement or repair or regeneration. Whatever the approach, the engineering of an architecture and of func-

tional characteristics that allow one to mimic a specific tissue is critical to achieving any success and to meeting the challenge of imitating nature. In fact, because of the interrelationship of structure and function in cells and tissues, it would be unlikely to have the appropriate functional characteristics without the appropriate three-dimensional architecture. Thus, many of the chapters in this book describe in some detail the approach being taken in the design and engineering of constructs for specific tissues and organs, and any further discussion of this is left to those chapters.

The challenge of imitating nature, however, does not stop with the design and engineering of a specific tissuelike substitute or a delivery vehicle. This is because the patient need that exists cannot be met by making one construct at a time on a benchtop in some research laboratory. Accepting the challenge of imitating nature must include the development of cost-effective manufacturing processes. These must allow for a scale-up from making one at a time to a production quantity of 100 or 1000 per week. Anything significantly less would not be cost effective; and if a product cannot be manufactured in large quantities and cost effectively, then it will not be widely available for routine use.

Much of the research on manufacturing technology has focused on bioreactor technology. A bioreactor simply represents a controlled environment — both chemically and mechanically — in which a tissuelike construct can be grown (Freed *et al.*, 1993; Neitzel *et al.*, 1998; Saini and Wick, 2003). The design of a bioreactor involves a number of critical issues. The list starts with the configuration of the bioreactor, its mass transport characteristics, and its scaleability. Then, if it is to be used in a manufacturing process, it is desirable to minimize the number of aseptic operations while maximizing automation. Reliability and reproducibility obviously will be critical, and it needs to be user friendly.

Although it is generally recognized that a construct, once implanted in the living system, will undergo remodeling, it is equally true that the environment of a bioreactor can be tailored to induce the *in vitro* remodeling of a construct so as to enhance characteristics critical to the success to be achieved when it is implanted (Seliktar *et al.*, 1998). Thus, the manufacturing process can be used to influence directly the final product and is part of the overall process leading to the imitation of nature. An important issue in developing a substitute for replacement, however, is how much of the maturation of a substitute is done *in vitro* in a bioreactor as compared to what is done *in vivo* through the remodeling that takes place within the body itself, i.e., in the body's own bioreactor environment. As pointed out by Dr. Frederick Schoen (private communication), in this one needs to recognize that the rate at which remodeling *in vivo* takes place will be extremely different from individual to individual. It is equally true that the extent of remodeling also will be different. Thus, the degree of maturation

that occurs *in vivo* will be highly variable, depending on the host response.

Once a product is manufactured, a critical issue will be how it is delivered and made available to the clinician. The Organogenesis product, Apligraf<sup>TM</sup>, is delivered fresh and originally had a 5-day shelf life at room temperature (Parenteau, 1999), although recently this has been extended. On the other hand, Dermagraft<sup>TM</sup>, the skin substitute developed by Advanced Tissue Sciences, is cryopreserved and shipped and stored at  $-70^{\circ}\text{C}$  (Naughton, 1999). This provides for a much more extended shelf life but introduces other issues that one must address. Ultimately, the clinician will want off-the-shelf availability, and one way or another this will need to be provided if a tissue-engineered product or strategy is to have wide use. Although cryobiology is a relatively old field and most cell types can be cryopreserved, there is much that still needs to be learned if we are successfully to cryopreserve three-dimensional tissue-engineered products.

#### IV. INTEGRATION INTO THE LIVING SYSTEM

The final challenge to imitating nature is presented by moving a tissue-engineering concept into the living system. Here one starts with animal experiments, and there is a lack of good animal models for use in the evaluation of a tissue-engineered implant or strategy. This is despite the fact that a variety of animal models have been developed for the study of different diseases. Unfortunately, these models are still somewhat unproved, at least in many cases, when it comes to their use in evaluating the success of a tissue-engineering concept.

In addition, there is a significant need for the development of methods to evaluate quantitatively the performance of an implant, and a number of concepts are being advanced (Guldborg *et al.*, 2003; Stabler *et al.*, 2005). This is not only the case for animal studies, but is equally true for human clinical trials. With regard to the latter, it may not be enough to show efficacy and long-term patency; it may also be necessary to demonstrate the mechanism(s) that lead to the success of the strategy. Furthermore, it is not just clinical trials that have a need for more quantitative tools for assessment; it also would be desirable to have available the technologies necessary to assess periodically the continued viability and functionality of a tissue substitute or strategy after implantation into a patient.

Also, one cannot state that one has successfully met the challenge of imitating nature unless the implanted construct is biocompatible. Even if the implant is immune acceptable, there can still be an inflammatory response. This response can be considered separate from the immune response, although obviously interactions between these two might occur. In addition to any inflammatory response, for some types of tissue-engineered substitutes thrombosis

will be an issue. This is certainly an important part of the biocompatibility of a blood vessel substitute.

Finally, important to the success of any tissue-engineering approach is the immune response and that it be immune acceptable. This comes naturally with the use of autologous cells; however, if one moves to nonautologous cell systems (as this author believes we must, at least in many cases, if we are to make the products of tissue engineering widely available for routine use), then the challenge of engineering immune acceptance is critical to our achieving success in the imitation of nature. Today we have immunosuppressive drugs, e.g., cyclosporine; however, transplant patients treated this way face a lifetime where their entire immune system is affected, placing them at risk of infection and other problems.

It should be recognized that the issues surrounding the immune acceptance of an allogeneic cell-seeded implant are no different than those associated with a transplanted human tissue or organ. Both represent allogeneic cell transplantation, and this means that much of what is being learned in the field of transplant immunology can help us understand implant immunology and the engineering of immune acceptance for tissue-engineered substitutes. For example, it is now known that to have immune rejection there must not only be a recognition by the host of a foreign body, but there also must be present what is called the *costimulatory signal*, or sometimes simply signal 2. It has been demonstrated that, with donated allogeneic tissue, if one can block the costimulatory signal, one can extend survival of the transplant considerably (Larsen *et al.*, 1996). There also is the chimeric approach, where one transplants into the patient from the donor both the specific tissue/organ and bone marrow. This suggests that perhaps in the future one will be able to use a stem cell-based chimeric approach. As an example, if one were to differentiate an embryonic stem cell both into the tissue-specific cells needed and into the cells required for implantation into the bone marrow, then from a single cell source one would create the chimerism desired.

Another approach is that of therapeutic cloning. Here a patient's DNA is transferred into an embryonic stem cell, which in turn is differentiated into the cells needed for a particular tissue-engineering approach. As attractive as this approach appears, many think it is unrealistic, simply because of the scarcity of eggs and embryonic stem cells. Furthermore, as our knowledge of immunology continues to advance, other approaches might make the need for therapeutic cloning disappear (Brown, 2006). Thus, strategies are under development, and these may provide greater opportunities in the future for the use of allogeneic cells.

## V. CONCLUDING DISCUSSION

If we are to meet the challenge of imitating nature, there are a variety of issues. These have been divided here into three different categories. The issue of cell technology

includes cell sourcing, the manipulation of cell function, and the use of stem cell technology. Construct technology includes the engineering of a tissuelike construct as a substitute or delivery vehicle and the manufacturing technology required to provide the product and ensure its off-the-shelf availability. Finally is the issue of integration into living systems. This has several important facets, with the most critical one being the engineering of immune acceptance.

Much of the discussion here has focused on the challenge of engineering tissuelike constructs for implantation. As noted earlier, however, equally important to tissue engineering are strategies for the fostering of remodeling and ultimately the repair and enhancement of function. As the field moves to the more complex biological tissues, e.g., ones that require innervation and vascularization, it may well be that a strategy of repair and/or regeneration is preferable to one of replacement.

As one example, consider a damaged, failing heart. Should the approach be to tissue engineer an entire heart, or should the strategy be to foster the repair of the myocardium? In this latter case, it may be possible to return the heart to relatively normal function through the implantation of a myocardial patch or even through the introduction of growth factors, angiogenic factors, or other biologically active molecules. Which strategy has the highest potential for success? Which approach will have the greatest public acceptance?

Even though short-term successes in tissue engineering may come from the convergence of biologics and devices, long term it is the generation of totally biologic products and strategies that must be envisioned. These will result in advances that include, for example, the following: *in vitro* models for the study of basic biology and for use in drug discovery; blood cells derived from stem cells and expanded *in vitro*, thus reducing the need for blood donors; an insulin-secreting, glucose-responsive bioartificial pancreas; and heart valves that when implanted into an infant grow as the child grows. In addition, the repair/regeneration of the central nervous system will become a reality. Furthermore, as one thinks about the future, medicine will move to being more predictive, more personalized, and, where possible, more preventive. It is entirely possible that we will be able to diagnose disease at a preclinical stage. In that event, the concept of inducing biological repair prior to the appearance of the clinical manifestations of disease becomes even more attractive.

Thus, the strategy being evolved in Atlanta, Georgia, by the Georgia Tech/Emory Center for the Engineering of Living Tissues, an engineering research center funded by the National Science Foundation, is one that more and more is placing the emphasis on repair and/or regeneration. It is moving beyond replacement that may provide the best opportunity to meet the challenge of imitating nature. Fundamental to this is understanding the basic biology, including developmental biology, even though the biological

mechanisms involved in adult tissue repair/regeneration are far different from those involved in fetal development. Furthermore, to translate a basic biological understanding into a technology that reaches the patient bedside will require a multidisciplinary, even an interdisciplinary, effort,

one involving life scientists, engineers, and clinicians. Only with such teams will we be able to meet the challenge of imitating nature, and only then can the existing patient need be addressed and will we as a community be able to confront the transplantation crisis.

## VI. ACKNOWLEDGMENTS

The author acknowledges with thanks the support by the National Science Foundation of the Georgia Tech/Emory Center for the Engineering of Living Tissues and the many

discussions with GTEC's faculty and student colleagues and with the representatives of the center's industrial partners.

### I. INTRODUCTION

In the early 1930s Charles Lindbergh, who was better known for his aerial activities, went to Rockefeller University and began to study the culture of organs. After the publication of his book about the culturing of organs *ex vivo* in order to repair or replace damaged or diseased organs, the field lay dormant for many years. Indeed, delivering respite to failing organs with devices or total replacement (transplant) became far more fashionable. Transplantation medicine has been a dramatic success. But in the late 1980s scientists, engineers, and clinicians began to conceptualize how *de novo* tissue generation might be used to address the tragic shortage of donated organs. The approach they proposed was as simple as it was dramatic. Biodegradable materials would be seeded with cells and cultured outside the body for a period of time before exchanging this artificial bioreactor for a natural bioreactor by implanting the seeded material into a patient. These early pioneers believed that the cells would degrade the material, and after implantation the cell-material construct would become a vascularized native tissue. Tissue engineering, as this approach came to be known, can be accomplished once we understand which materials and cells to use, how to culture these together *ex vivo*, and how to integrate the resulting construct into the body.

Most major medical advances take decades to progress from the laboratory to broad clinical implementation. Tissue

engineering was such a compelling concept that the process moved much faster. As we discuss later, the speed at which tissue-engineering solutions can be implemented is inherently faster than traditional drug development strategies. For this reason, coupled with what was probably unexplained exuberance, business investors saw an immediate role for industry in delivering tissue-engineered products to patients. Traditionally, new fields are seeded with foundational research, development, and engineering prior to implementation, but an apparent alignment of interests caused many to believe that companies could deliver products immediately and that the traditional foundational aspects could wait.

The race to clinical implementation of a tissue-engineered medical product began with the incorporation of Advanced Tissue Science (ATS) in 1987. ATS and Organogenesis, an early competitor, began their quest by focusing on seeding biodegradable matrices with human foreskin fibroblasts. In the early days, Organogenesis, Integra, and Ortec focused on bovine-derived scaffolds, while ATS focused on human-derived scaffolds. Other companies focused on developing tissue-engineering products using scaffold alone or cells alone. The path to implementation has been very different for each class of company, as is summarized later.

With hindsight, one might say that the choice of living-skin equivalents as a first commercial product was probably

driven by the willingness of the FDA to regulate them as Class III devices rather than biologics. This attractive feature of the products was supplemented by large predicted market sizes and the ease of culturing skin cells. As these products moved from the laboratory to the clinic, development issues such as which cells, materials, and bioreactors were supplanted with industrial challenges such as scale-up and immunocompatibility.

At the same time that ATS and Organogenesis were rapidly growing, the view emerged that delivery of tissue-engineered products to patients would require an allogeneic off-the-shelf solution having ease of use and long storage life in the United States—and persists today. This business-driven decision predated development of allogeneic, cell-based therapies. Interestingly, in a study sponsored by the National Science Foundation, the World Technology Evaluation Center discovered that non-U.S. investors were focused on autologous cell therapies resulting from a belief that allogeneic therapy would be unsuccessful because of the need to suppress the patient's immune system. This difference in emphasis between U.S. and non-U.S. investors continues today. Both approaches have genuine advantages and disadvantages. However, once it became clear that cell-seeded scaffolds could trigger dramatic changes in natural wound healing, thereby inducing *de novo* tissue formation and function, clinical implementation through industry progressed from skin to a wide array of tissues. In addition, pockets of excellence arose at major medical centers, where new innovations were tested clinically in relatively small numbers of patients.

So one is left with several questions: What have we learned from these early adoptions of tissue engineering? How can these lessons drive sustainable innovation that will both heal and generate a return on investment? Is broad clinical implementation of tissue engineering limited by the nature and structure of regulatory bodies? This chapter seeks to answer these questions by looking historically at selected high-profile clinical tissue-engineering programs and looking forward with a suggested generic approach to rapid clinical translation in this new era of advanced medical therapies.

## II. HISTORY OF CLINICAL TISSUE ENGINEERING

### What Is Clinical Tissue Engineering?

As mentioned earlier, in the early 1990s the term *tissue engineering* was generally used to describe the combination of biomaterials and cells *ex vivo* to provide benefit once implanted *in vivo*. What emerged over the next decade, however, were biomaterials designed to alter the natural wound-healing response and cell-only therapies. Lessons learned in the development of each led to the fusion of these tools under the rubric of tissue engineering.

Today, there remains confusion about what the term *tissue engineering* truly encompasses. A related term, *regenerative medicine*, has emerged recently. The boundaries of what falls under each of these terms are unclear. We do not seek to provide a definitive answer in this chapter, but herein we discuss the use of biomaterials and cell-seeded biomaterials. We exclude the use of cell-only therapies. Thus, we define *clinical tissue engineering* as “the use of a synthetic or natural biodegradable material, which has been seeded with living cells when necessary, to regenerate the form and/or function of a damaged or diseased tissue or organ in a human patient.” We see clinical tissue engineering as a set of tools that can be used to perform regenerative medicine, but not all regenerative medicine has to be done with that set of tools.

### Two-Dimensional Clinical Tissue Engineering

The earliest clinical applications of tissue engineering revolved around the use of essentially flat materials designed to stimulate wound care. Tissue-engineered skin substitutes dominated the market for almost a decade. Another small and slim tissue that found a clinical application was cartilage. Later in the 1990s thin sheets of cells were produced in culture and then applied to patients using a powerful cell-sheet technology. In both the applications, engineered tissue equivalent is relatively easy to culture *ex vivo* because oxygen and nutrient delivery to thin, essentially two-dimensional, materials is not challenging. In addition, once the construct has been cultured *ex vivo*, integration into the body is not an insurmountable barrier for thin materials.

### Tissue-Engineered Skin Substitutes

Since the inception of tissue engineering there has been a focus on the regeneration of skin. A number of drivers led to this early focus, not least of which was the mistaken assumption that skin is simple to reconstitute *in vitro*. Skin cells proliferate readily without signs of senescence. Indeed, fibroblasts and keratinocytes have been cultured *in vitro* for many years with ease. Interestingly, other highly regenerative tissues, such as the liver, are populated with cells that cannot be proliferated *in vitro*. The clinical need for effective skin wound healing was also a major driver. One in seven Medicare dollars is spent on treating diabetes-induced disease in the United States. The largest component of that cost goes toward treating diabetic ulcers. This attractiveness drew many tissue-engineering efforts into the wound-care market.

### Regenerative Biomaterials

For almost two decades scientists have explored the use of processed natural materials as biodegradable scaffolds that induce improved healing from skin wounds. One of the first products to market was the INTEGRA® Dermal Regen-

erationTemplate. INTEGRA® is an acellular scaffold designed to provide an environment for healing using the patient's own cells. The INTEGRA® label describes the product as follows:

INTEGRA® Dermal Regeneration Template is a bilayer membrane system for skin replacement. The dermal replacement layer is made of a porous matrix of fibers of cross-linked bovine tendon collagen and a glycosaminoglycan (chondroitin-6-sulfate) that is manufactured with a controlled porosity and defined degradation rate. The temporary epidermal substitute layer is made of synthetic polysiloxane polymer (silicone) and functions to control moisture loss from the wound. The collagen dermal replacement layer serves as a matrix for the infiltration of fibroblasts, macrophages, lymphocytes, and capillaries derived from the wound bed. As healing progresses an endogenous collagen matrix is deposited by fibroblasts, simultaneously the dermal layer of INTEGRA® Dermal Regeneration Template is degraded. Upon adequate vascularization of the dermal layer and availability of donor autograft tissue, the temporary silicone layer is removed and a thin, meshed layer of epidermal autograft is placed over the "neodermis." Cells from the epidermal autograft grow and form a confluent stratum corneum, thereby closing the wound, reconstituting a functional dermis and epidermis.

INTEGRA® is now one of many processed natural materials used to stimulate healing. Since the material is not vascularized at point of use, it is best used in thin (two-dimensional) applications. INTEGRA® is an FDA-approved tissue-engineering material widely used in patients today. INTEGRA® does not, however, contain biological factors that are released during the tissue-remodeling process.

Another class of products, the thin extracellular matrix-based materials, does release natural factors as the material degrades, and these factors serve to reset the natural tissue-remodeling process, thereby producing a healing outcome. The most common ECM-based material is derived from the submucosal layer of pig small intestine. The Cook OASIS® Wound Matrix label describes the product as follows:

The OASIS® Wound Matrix is a biologically derived extracellular matrix-based wound product that is compatible with human tissue. Unlike other collagen-based wound care materials, OASIS is unique because it is a complex scaffold that provides an optimal environment for a favorable host tissue response, a response characterized by restoration of tissue structure and function. OASIS is comprised of porcine-derived acellular small intestine submucosa. The OASIS Wound Matrix is indicated for use in all partial- and full-thickness wounds and skin loss injuries as well as superficial and second-degree burns.

Regenerative biomaterials, or materials designed to alter and enhance the natural tissue-remodeling process, are being used in hundreds of thousands of patients worldwide. These materials recruit a patient's own cells into the healing process postimplantation, and their relative

simplicity makes them compelling clinical tools for indications where a thin, essentially two-dimensional material will achieve the desired result. In an elegant series of accomplishments, natural matrices have been applied for skin wounds and many other tissue-replacement therapies.

### Cell-Seeded Scaffolds (Fig. 3.1)

Cultured skin-substitute products, where cells are seeded onto a biodegradable matrix and cultured *ex vivo* prior to shipment and use, have been extraordinarily difficult to market. Given this reality, it is interesting that the purveyors of the two leading skin equivalents are the true early pioneers of tissue engineering. Both Advanced Tissue Sciences and Organogenesis engaged in a valiant effort to use human fibroblasts and biomaterials to regenerate skin. They were challenged by a changing regulatory landscape, an ongoing struggle with reimbursement issues, and the highly complex need to manufacture and ship a living product. A full case study of ATS or Organogenesis would be of tremendous value to the next generation of tissue-engineering companies but is beyond the scope of this chapter. Dermagraft®, the Advanced Tissue Science product now manufactured by Smith & Nephew, uses skin cells

FIG. 3.1.

FIG. 3.2.

isolated from neonatal foreskins prior to seeding onto a polymeric scaffold. Apligraf®, Organogenesis' product, used similar technology to seed and culture cells on collagen-based scaffolds. Tissue-engineered skin equivalents continue to be developed. As technology improves and multilayer systems progress to broad clinical use, the market should also increase from today's anemic levels of \$15 million/year. The FDA and reimbursement issues have greatly impacted clinical use of cultured skin equivalents. The FDA treated these products as devices yet held them to biologic standards, and this led inevitably to their being reimbursed as biologics.

Another approach to clinical skin remodeling is using autologous cell-based therapies (Fig. 3.2). One attractive feature of using a patient's own cells is, of course, the lack of an immune response, but the manufacture of patient-specific yet inexpensive skin replacements is very complex. Epicel® from Genzyme Biosurgery uses irradiated mouse fibroblasts as a feeder layer from which to grow patient-specific keratinocytes. Co-culture with animal-derived cells may raise regulatory and infectious disease questions requiring manufacturing practices that increase the cost of goods.

### Cartilage (Fig. 3.3)

In 1995, Genzyme began expanding patient-specific chondrocytes. Small biopsies were sent to Genzyme, where they were cultured and returned to the surgeon for implantation. The product, Carticel®, was approved as a biologic by

FIG. 3.3.

the FDA in 1997. At time of treatment, a patient typically receives 10 million to 15 million cells after five weeks of custom *ex vivo* culturing. As with skin remodeling, a number of companies have focused on the use of acellular regenerative materials. Approved products are currently sold in many countries around the world that are based on collagen and/or extracellular matrixes (ECMs). Thousands of patients around the world have benefited from orthobiologic approaches to cartilage replacement. Although patient-specific cartilage replacement therapy has also provided benefit, it is a good example of the difficulty of delivering individualized therapies while deriving a profit. The considerable infrastructure required to culture tissue safely in this manner presents unique challenges for the manufacturer to overcome. Many research groups around the world have sought to improve on the efficacy of Carticel®, focusing on cell-based and regenerative material-based approaches. Although cartilage segments *in vivo* and *in vitro* are generally small and non-vascularized, the biomechanical properties of those tissue-engineered cartilage products overall have not achieved the standards required for clinical application.

### Corneal Cell Sheets (Fig. 3.4)

Okano at Tokyo Women's Hospital has invented a remarkable technology that produces intact cell sheets for clinical application. In general, when human cells are cultured *in vitro* they adhere to their culture dish substrate. Traditional culturing techniques extract cells by adding enzymes and other materials that digest cell-surface and

FIG. 3.4.

cell-cell contacts. Cells processed in this manner are delivered as single cells for clinical application. Okano envisioned an alternative for removing cells that has had a dramatic clinical impact. Okano covalently bonds a layer of *N*-isopropylamide to the surface of the culture dish prior to adding cells and has shown that, under normal growth temperatures, cells adhere but that when slightly chilled, the entire sheet of cells is repelled from the dish without disrupting the cell-cell contacts and can be lifted from the surface rather like a Post-it note®. For a first clinical application, Okano's team cultured corneal epithelial cells and used the resulting sheets to replace the damaged corneal epithelia of dozens of patients. Okano has reported significant success and, although the number of patients in need of corneal epithelial replacement is limited, this cell-sheet technology has real potential for broader clinical tissue-engineering application.

#### Encapsulated Pancreatic Islets

The use of biomaterials to immunoisolate pancreatic islets of Langerhans has been studied since the mid-1990s. If one could build a cage that surrounded the islet and had a mesh size small enough to prevent the approach of antibodies to the islet but large enough to enable nutrient diffusion, it may be possible to diminish a patient's dependence on insulin posttransplant. Alginate-encapsulated islets have been studied for many years, and an ongoing clinical trial (Novocell) is using interfacially polymerized PEG-encapsulated islets (Fig. 3.5). The success of these trials is not yet known, but porcine islets have already been shown to be protectable in a short-term discordant xenotransplantation model. Interestingly, our own work has shown that even a molecular-scale PEG cage can immunoisolate islets,

FIG. 3.5.

and this has now been shown to eliminate insulin dependence in diabetic animals.

### Three-Dimensional Clinical Tissue Engineering

#### Bone Regeneration

Since the turn of the century, Dr. Yilin Cao has led a remarkable clinical tissue-engineering approach to craniofacial reconstruction in Shanghai, China. Regeneration of craniofacial bone in patients has now been reported by using demineralized bone and autologous cells. Using

tissue engineering to rebuild lost bone is novel, but it is not the only regenerative medicine approach being applied to the challenge. Peptide-based therapy is an established treatment for stimulating bone formation. Bone morphogenetic protein (BMP) is the most common drug currently employed to induce bone growth. In a novel application of BMP, Medtronic developed a spine fusion device containing a collagen sponge infused with the peptide that is now in clinical use (Fig. 3.6). Deployed in the spine, the device and BMP induce native bone to fill the cavity within the device. Although not often identified as such, this combination of a biodegradable material and a tissue-formation-inducing biologic molecule is clinical tissue engineering at its best.

### Bladder

Early successes in the tissue-engineering field were gained in relatively simple tissue structures, organizations, or functions, such as chondrocytes, or two-dimensional cellular structures with limited organ function required. Tengion advanced a technology pioneered by Anthony Atala to augment or replace failing three-dimensional internal organs and tissues, requiring functionality and a vascularization platform using autologous progenitor cells, isolated and cultured *ex vivo*, and seeded onto a degradable biomaterial optimized for the body tissue it is intended to augment or replace. This cell-seeded neo-organ construct is implanted into the patient for final regeneration of the neo-organ

(Fig. 3.7). Using the neo-organ construct as a template, the body regenerates healthy tissue, restoring function to the patient's failing organ. This autologous organ and tissue regeneration avoids many of the negative implications of traditional donor transplantation techniques, such as requisite immunosuppression and limited donor supply.

Tengion's initial focus on the genitourinary system was based on a bladder augmentation and ultimately an organ replacement for patients who have undergone radical cystectomy, or removal of the bladder. Tengion developed a robust focus on manufacturing capabilities to support neo-organ construct production in accordance with regulatory standards.

### Blood Vessel

At Tokyo Women's Hospital, Dr. Toshi Shin'Oka has used patient-specific tissue engineering to replace malformations of pediatric pulmonary arteries. Working with a biodegradable matrix designed by one of the "fathers" of biomaterials, Dr. Ikada, Shin'Oka seeded a tubular material with the patient's own bone marrow cells at the time of vessel reconstruction (Fig. 3.8). In a series of clinical experiments, Shin'Oka demonstrated that biodegradable scaffold's strength during the degradation period was sufficient to allow complete natural vessel replacement without rupture. This first successful clinical replacement of a pediatric blood vessel with a tissue-engineered construct designed to become as natural as the patient's own vasculature was performed in almost 50 patients.

As one considers these historical events and the advances in tissue engineering over the past 80 years, we are seeing that tissue engineering is moving toward the regeneration and repair of increasingly complex tissues and even whole-organ replacement. This field holds the realistic promise of regenerating damaged tissues and organs *in vivo* (in the living body) through reparative techniques that stimulate previously irreparable organs into healing themselves. Regenerative medicine also empowers scientists to grow tissues and organs *in vitro* (in the laboratory) and safely implant them when the body is unable to be prompted into healing itself. We have the technological potential to develop therapies for previously untreatable diseases and conditions. Examples of diseases regenerative medicine could cure include diabetes, heart disease, renal failure, and spinal cord injuries. Virtually any disease that results from malfunctioning, damaged, or failing tissues may be potentially cured through regenerative medicine therapies. Having these tissues available to treat sick patients creates the concept of *tissues for life* (U.S. Department of Health and Human Services, 2005).

## III. STRATEGIES TO ADVANCE TOWARD THE CLINIC

Since the mid-1980s we have had many opportunities to learn how one might quickly convert tissue-engineering

FIG. 3.6.

**FIG. 3.7.**

technology into regenerative medical products from the bench to the bedside. Establishing a plan to move toward clinical testing rests on a strategy of defining the unmet medical need (patient population), determining the intended use of the tissue-engineered/regenerative medical product (TERMP) that addresses the need, and defining the processes necessary to ensure that the product can be reproducibly manufactured to be both safe and effective once it is placed into the patient. A requisite scientific basis for partial or complete structural and/or functional replacement of a diseased organ or tissue requires a definition of what constitutes a successful outcome (i.e., primary clinical endpoint). Ultimately, any clinical testing will require the application of existing regulatory guidelines for testing and manufacturing a product prior to use in a human subject. With this information in hand, initial steps into clinical testing phases can be contemplated. As we have already seen, sound scientific

strategies are not effective in clinical translation unless there is a balancing sustainable business strategy. Naturally, the scientific and business strategies must be woven together, in terms of both specific outcomes and timelines. As we discuss in detail later, the significant differences between traditional drug therapies and tissue-engineering therapies actually offer the opportunity to accelerate the bench-to-bedside process. We take the position that instead of a 10- to 15-year development cycle, tissue-engineering therapies can be brought to market in 8–10 years.

In considering the exploratory clinical testing phase with a scientifically based program, final product characteristics must be defined as well as standardizing the production processes and anticipating what justifications will indicate readiness for entering into the next phase of clinical testing (confirmatory studies). Table 3.1 presents an overview of a prototypical product development process.

FIG. 3.8.

Transitioning into an initial exploratory clinical evaluation rests on understanding the objectives for the first regulatory review as they relate to the specific product characteristic, the process to make the product, translational medical study results, and how preclinical information demonstrates the desired clinical outcome (Preti, 2005; Weber, 2004). In a rapidly changing field where regulatory agencies are still maturing in their decision-making processes, the decisions made during the initial clinical evaluation phase can have far-reaching impact. Table 3.2 provides an overview of data that will be needed prior to entering into an exploratory clinical trial.

Regulatory considerations affect the types of data required and process technologies that must be in place prior to initiating clinical trials. Indeed, the regulatory environment is much more defined today than in the early days of tissue engineering because of scientific advances and insights gained from various attempts to commercially develop tissue-engineering and regenerative medical products. Once again, understanding the regulatory environ-

ment is foundational to implementing successfully the development plan and using the scientific objectives laid out in Tables 3.1 and 3.2.

Several regulatory considerations have significant impact on the development plan necessary to bring a TERMP to clinical testing: extent of cellular manipulation, cell source and use, and scaffold characteristics (Table 3.3). With a scientific foundation, an established product characterization, and application of appropriate regulatory considerations established, three additional considerations come into play for a particular technology to be transitioned from the bench to the bedside: raw materials testing, manufacturing process controls testing, and translational medicine.

## Raw Materials Testing

### Cells

Cellular components of a TERMP are raw materials encompassing viable cells from the patient (autologous), other donors (allogeneic), or animals (xenogeneic). Standards

**Table 3.1.** Overview of a potential testing program to support clinical entry of a prototypical tissue-engineered/regenerative medical product (TERMP)**Cellular/chemistry manufacturing control**

- Define product production and early manufacturing processes
- Establish cell, tissue, and biomaterial sourcing for good manufacturing practices (GMPs)
- Validate product processing and final product testing scheme
- Characterize adventitious agents and impurities for each element
- Define lot-to-lot consistency criteria
- Validate quality control procedures

**Translational medical studies**

- Complete *in vitro* and *in vivo* testing
- Define toxicity testing of raw materials composing the TERMP
- Evaluate biomaterial biocompatibility
- Establish immunogenic and inflammatory responses to each component
- Develop rationale for animal and *in vitro* models to test product effectiveness
- Define endpoints for establishing TERMP durability

**Clinical trials**

- Develop rationale for safety and clinical benefit (risk/benefit analysis)
- Design exploratory and confirmatory trials
- Select patient population and define inclusion/exclusion criteria
- Identify investigational comparators and control treatments
- Establish primary and secondary study endpoints
- Consider options for data analysis and potential labeling claims

for cellular quality have been extensively reviewed and considered by regulatory bodies and generally focus on controlling introduction of infectious diseases and cross-contamination from other patients. These standards also consider potential for environmental contamination from the facility and equipment and the introduction of infectious agents from materials used to process cells (e.g., bovine-derived material that may contain infectious agents).

For TERMPs that have cells placed onto a scaffold, scientific and regulatory considerations focus on ensuring that both the raw materials comprising the scaffold and its three-dimensional characteristics are biocompatible (FDA, 1995). Biocompatibility testing involves evaluation of the scaffold's potential cytotoxicity to cells being seeded, potential toxic-

ity that may be inflicted on the recipient's tissues once implanted, as well as the consequences of immune and inflammatory responses to the TERMP after implantation. Biocompatibility extends through the *in vivo* regeneration process; therefore, biocompatibility should be evaluated in parallel with demonstrating that the scaffold maintains the necessary biomechanical properties to support new tissue or organ growth.

**Scaffold**

Synthetic, natural, or semisynthetic materials are readily available from various commercial sources, but the quality control of a material varies substantially between medical and research grades. As testing of a potential TERMP moves from research bench to clinical testing, scaffold composition and designs must be controlled for reproducibility of production and product characterization. Final production must consider quality management and organization, device design, production-facility environmental controls, equipment, component handling, production and process controls, packaging and labeling control, distribution and shipping, complaint handling, and records management, as outlined in 21 CFR 820 (FDA, 2005b). However, during the exploratory phase and transition from bench to clinical testing, the most relevant of these guidelines are process validation and design controls.

Typically, a design input phase is a continuum beginning with feasibility and formal input requirements and continuing through early physical design activities. Engineering input on final prototype specifications follow the initial design input phase and establish the design reviews and qualification. For a combination TERMP, defining quality for the chemical polymer (e.g., PGA) or natural

**Table 3.3.** Regulatory considerations for the development of a tissue-engineered/regenerative medical product

	<i>Description</i>	<i>Impact</i>
Manipulation of cells	For structural and nonstructural tissues, manipulation is minimal if it involves centrifugation, separation, cutting, grinding and shaping, sterilization, lyophilizing, or freezing (e.g., cells are removed and reintroduced in a single procedure). Manipulation is not minimal if cells are expanded during culture or growth factors are used to activate cells to divide or differentiate. Defined in 21 CFR 1271.3(f) — see also FDA (2005a)	More extensive regulatory requirements applied to TERMP when manipulation is more than minimal.
Cell source and application	Homologous use is interpreted as the augmentation tissue using cells of the same cellular origin. Examples include applying bone cells to skeletal defects and using acellular dermis as a urethral sling. Nonhomologous-use examples include using cartilage to treat bladder incontinence or hematopoietic cells to treat cardiac defects. Defined in 21 CFR 1271.3(c) — see also FDA (2001).	Nonhomologous use triggers additional requirements for entering clinical trials.
Scaffold characterization	Final scaffold composition and design determine whether the TERMP is characterized as a device, a biologic, or a combination product. Defined in Quality Systems Regulations (QSRs) in 21 CFR 820 (FDA, 2005b) — see also FDA (1999).	Devices are held to the QSRs in 21 CFR 820 (FDA, 2005b), biologics are required to comply with good manufacturing processes (GMPs) (FDA, 1991), and combination products are often required to comply with both sets of regulations and guidelines.

material (e.g., collagen), including any residues introduced during machine processing (e.g., mineral oil), can require QSR integration into a product that would otherwise be regulated as a biologic. Since many TERMPs are combination products, testing of scaffold, cells, and the cell-seeded scaffold (i.e., construct) are required to ensure that, in exploratory clinical trials, the product is sterile, potent, fit for use, and composed of the appropriate raw materials to function properly following *in vivo* placement.

## Manufacturing Process Controls and Testing

### Cellular Processing

In-process controls generally focus on sterility, viability, and functional analysis of cells from isolation, through expan-

sion and before they are placed on the scaffold. Release criteria generally ensure that cells remain viable and functioning properly after being attached to the scaffold. Functional evaluations of cells and potency assessments of their “fitness for use” are performed after cells are combined with (or seeded onto) a scaffold. Taken together, these tests determine whether the final product can be released from the production facility for surgical implantation in the clinical setting.

### Biomaterial Process and Testing

The focus of biomaterial process testing is to evaluate the *in vivo* behavior of the scaffold material following implantation. Characterizing the scaffold degradation profile ensures that breakdown time and other degradation attributes will support the regenerating tissue long enough

for it to acquire the appropriate functional and structural integrity as the scaffold material degrades. Defining scaffold-breakdown products identifies the biochemical factors that may impact reparative, inflammatory, immunologic, and regenerative processes once the product is placed into the body. Measuring biomechanical properties such as stress-strain relationships, Young's modulus, and other characteristics ensures that the scaffold portion of the combination product will perform properly during the *in vivo* regenerative phase.

### Final Combination Product Testing

Analytical methods for final product testing vary substantially, depending on the composition of the TERMP. In general, any product intended for customization to individual patients (e.g., autologous products) requires confirmation that release and potency standards are met via nondestructive test methods. Such test methods are typically novel and specific to each product type and are frequently based on a battery or "matrix" of tests that evaluate cellular function and physical parameters of the scaffold. In contrast, lot-testing strategies, statistical sampling, and more routine analytical methods are available for scaffold-only products and cell-based products produced in large lots (e.g., allogeneic and xenogeneic cellular products). In the future we may see allogeneic therapies that are customized for patient-specific needs. Naturally, such innovations will require a combination of analytic approaches.

### Translational Medicine

Safety and efficacy evaluation of a TERMP is conducted in animals, and the findings are foundational to designing the first clinical trial protocol. These translational studies are the basis for safely transitioning a potential product into clinical testing. Since the regenerative process invoked by components product involve multiple homeostatic (e.g., metabolic), defense (e.g., immune), and healing (e.g., inflammation) pathways, animal studies provide an approach to understanding the inherent function of the TERMP (i.e., if the product contains cells, it can be considered a living "tissue") and the inherent response of the body to a product composed of biomaterials with or without cells. Animal studies are a regulatory necessity, but we must also remind ourselves that many therapies function effectively in animals and fail in humans. The reverse is not often discussed. Some therapies may fail preclinical testing and never enter clinical trials, but this is not to say that some of those therapies would not be excellent when applied in humans. An interesting example of this conundrum is emerging in artificial-blood therapies. The U.S. Army received approval for clinical use of a natural blood substitute in trauma applications during war. In a postapproval attempt to understand why the product worked so effectively in humans it was tested in a porcine model of hemorrhagic shock. The pigs did not do well with the therapy. The investigators proceeded to test the product in rodents and

demonstrated that the rodents died when injected with the blood substitute that worked so effectively in the clinic. If preclinical animal testing had been performed first, this excellent product would never have been submitted for clinical evaluation.

Translational medical studies can be conducted in large animals (e.g., dog) or small (e.g., rat). Selection of the correct animal model should be based on the similarities of the pathophysiology, physiology, and structural components intended for treatment in the clinical setting. Exploratory clinical trials for most medical products utilize normal human volunteers as the first line of clinical testing. However, some products can be tested outside of the intended clinical population. As such, the animal model employed in translational medicine should resemble the human condition as closely as possible — immune status, inflammatory response, and healing pathways as well as the medical approaches used to treat the human condition (e.g., surgical procedure) and monitoring methods to follow a clinical benefit or risk (e.g., imaging).

Many pivotal preclinical experiments are performed in academia, and the importance of complying with the good laboratory, manufacturing, and tissue practice regulatory standards is critical at this phase. There is no such thing as GLP/GMP/GTP-light, and many academic animal facilities are not compliant to the degree needed by the FDA. This issue will increase in significance as the FDA increases its post-approval auditing of preclinical compliance.

Since the regenerative response starts at the moment of TERMP implantation and concludes with the final functioning neo-tissue or neo-organ, animal studies provide an understanding of how to evaluate the early body responses as well as longer-term outcomes reflecting the desired benefit — an augmented or replaced tissue or organ. Since most products are surgically implanted for the life of the patient, the duration of a translational study would extend to the time when final clinical outcome is achieved. Regulatory agencies have given considerable thought to the duration of translational studies, and many are of long duration — months to years. Nonetheless, since the final outcome is frequently achieved in a shorter period of time, the potential to conduct shorter-duration studies based on final patient outcome may present a rational solution to testing clinical utility in the shortest possible time while ensuring a high benefit:risk outcome.

Understanding which endpoints are available and appropriate for clinical testing is achieved through translational studies. Standards are provided for the proper safety evaluation of TERMPs, whether they are regulated as a device (FDA, 1997) or a biological product (e.g., 351 or 361). Although the optimal testing strategy will typically be product specific (FDA, 2001), some basic guidelines for testing device-like products can be found in the ISO10993-1 guidance document. These testing guidelines cover a number of *in vitro* and *in vivo* assays (Table 3.4).

A scaffold-only product that is similar to an already-tested material or medical device can be accelerated through the testing process using a 510K approach under an existing PMA (Rice and Lowery, 1995). Appropriate translational testing approaches will follow the biocompatibility flow-chart for the selection of toxicity tests for 510(k)s (FDA, 1995).

If the device requires an IDE/PMA level of testing, then the translational studies will be more extensive and influenced by the length of time that the TERMP is in contact with the body of the recipient. As already mentioned, many regenerative medical devices or the tissues that replace the initial implant are in bodily contact for longer than 30 days and are therefore considered permanent devices. These products require a full range of *in vitro* and *in vivo* testing approaches prior to clinical testing.

If the TERMP is cell based or the primary mode of action is mediated through the cellular constituents of a scaffold-cell combination product, then the device requires an IND/BLA. The testing approach for these products will usually involve an assortment of studies that evaluate scaffold and cellular components through appropriate endpoint selection and experimental design for both *in vitro* and *in vivo* translational studies. An example of a preclinical development program for a cell-based product is presented in Table 3.5.

Although specific testing approaches are not defined absolutely, the scope and testing approaches for a specific TERMP can frequently be predicted by evaluating the development approach used for related technology platforms. A number of tissue-engineering technologies can bridge from bench to clinical application. Testing a TERMP prior to moving into clinical evaluation is based on (i) scientific

information demonstrating that the potential clinical product can invoke a response in the body of potential therapeutic benefit; (ii) demonstration of a controlled and reproducible manufacturing process; and (iii) demonstration of the safety of each component and the final product. This stage in the development of a prototypical clinical product is typically the first point of regulatory authority and governance body interactions and an area where procedural approaches for establishing controls are frequently reviewed and clarified.

IV. BRINGING TECHNOLOGY PLATFORMS TO THE CLINICAL SETTING (Fig. 3.9)

General

Technology platforms that intend to recapitulate a tissue (e.g., skeletal muscle, bone, cardiac muscle) or an organ may address a range of unmet medical needs, from simple cosmetic defects in the body (tissue-focused technologies) to life-threatening maladies (organ and organ system replacement). Bringing a TERMP technology to clinical testing may rest on the scope of unmet medical need and the availability of alternative therapies. The array of available alternative therapies influences the early testing strategy of a particular product by determining comparable products to be evaluated, selection of animal models, appropriate endpoints and amount of preclinical information needed to enter into clinical testing. Ultimately, the safety and efficacy of the prototype product are balanced by a risk:benefit analysis versus other available products, which directly influences the ability to test it in human trials.

Table 3.4. Test categories described in ISO10993-1

<i>In vitro</i> assays	<i>In vivo</i> assays
Cytotoxicity	Irritation
Pyrogenicity	Sensitization
Hemocompatibility	Acute systemic toxicity
Genotoxicity/genetic tests	Subchronic toxicity
	Local tolerance

Tissue-Focused Technologies

Tissue-focused technologies, such as bone and tendon repair, may move into clinical testing through routes that have been established by previous successes (e.g., Depuy's Restore®). If animal models and alternative therapeutic approaches are established, comparing the benefit of a proposed product to an existing therapy may be an appropriate approach to potential clinical testing. Ultimately, comparing the benefit of the TERMP versus the "gold standard"

Table 3.5. General translational medical testing paradigm for a cell-based tissue-engineered/regenerative medical product

<i>Cellular component</i>	<i>Scaffold</i>	<i>Combination</i>
Phenotype characterization	Early stage (acute)	Early stage (acute toxicity)

	Biomechanical properties	
	Degradation profile	

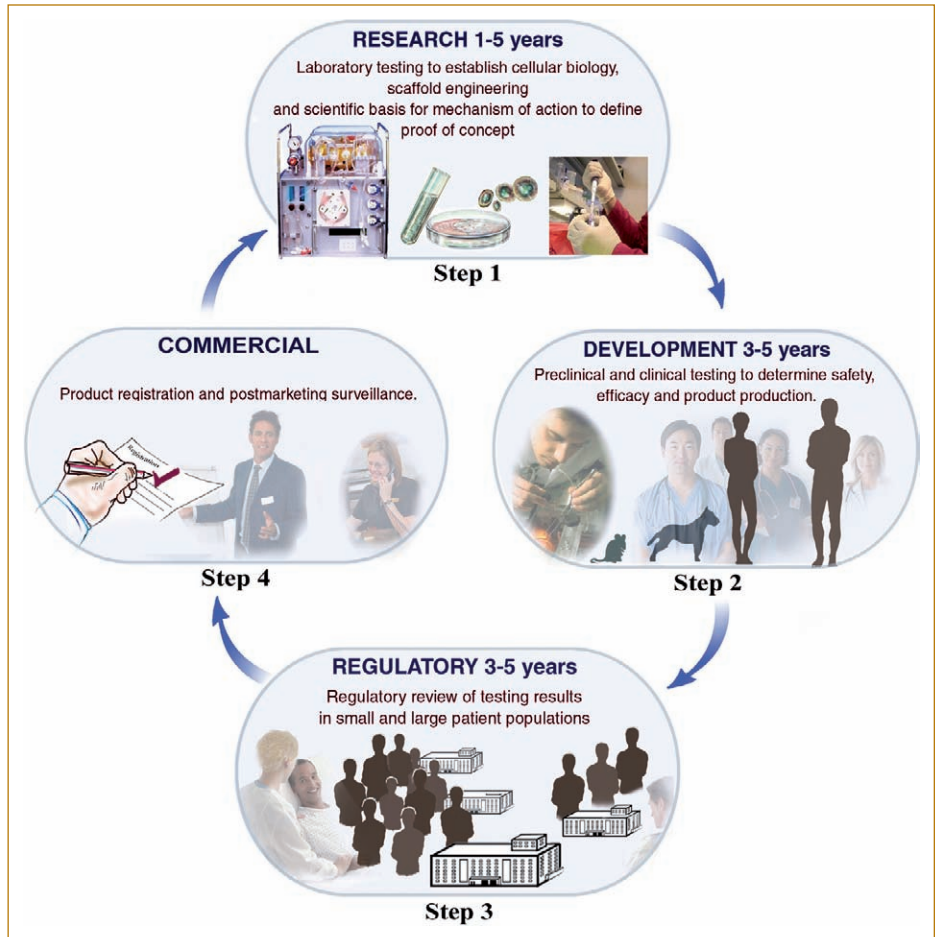

FIG. 3.9.

commercial product or surgical therapy is the foundational rationale to evaluate potential human use.

Depending on the raw materials composing the TERMP, the primary mode of action may drive the testing strategy for novel products. The primary mode of action is defined by the scientific studies demonstrating the range of bodily responses invoked by the product and the range of long-term outcomes. Products that elicit an immune response (e.g., allogeneic, xenogeneic, or genetically modified cells) will need to include an evaluation of immunotoxicity, immunomodulation, and/or potential for rendering the recipient sensitive to infectious diseases. Those products whose production employs animal materials will require testing for adventitious infectious agents or the use of materials from certified sources. Testing for potential endogenous infectious agents prior to clinical testing is especially relevant for products that contain, or whose production process includes, xenogeneic cells. Products using scaffold material for which there is little or no previous human testing will require testing that follows established FDA Guidelines (see G95-1) (FDA, 1995). Biodegradable scaffolds have a testing paradigm similar to that used for a nonbiodegradable material, with additional requirements for defining the degrada-

tion profile, breakdown products released, route of excretion, and response of the body to the material as it breaks down. Ultimately, the final safety/efficacy testing strategy may rest with the regulatory pathway selected through a process established by the “Office of Combination Products.”

### Organ-Based Technologies

Tissue-engineered/regenerative medical technologies offer the promise of alleviating the vast organ shortage that exists worldwide. In spite of this great promise, the pathway to clinical testing with a product that replaces an entire organ is the least clearly defined. Although the clinical benefit of such a TERMP may be definitive, the endpoints readily discernible, and the animal models established, the delivery mechanism, procedures for connecting the neo-organ to other parts of the body, may pose substantial development hurdles and actually preclude clinical testing.

The complexity of whole-organ replacement by these types of products spans defining what is actually being replaced through defining what ancillary products may be needed if all organ functions are not included in the product characteristics. Traditional therapeutic approaches have

generally focused on one pathway or target (e.g., pharmaceutical) or possibly two therapeutic benefits, such as structural and functional restoration (e.g., cartilage repair products). However, those products replacing an entire organ (e.g., kidney) or body part (e.g., limbs) will need to consider broad functional testing of both exocrine/excretory and endocrine functions before clinical testing can be considered.

The transition to clinical testing of more complex TERMPs will have commensurate preclinical testing requirements to demonstrate not only the functionality of each component being replaced or augmented, but also the biological responsiveness of the integrated organ to native homeostatic mechanisms (e.g., integration with blood pressure or glucose control). Matters such as percutaneous conduits, skin infections, and controlling biofilms may be substantial development hurdles for the use of products outside the body. For products intended to be used inside the body, solutions for vascular connections, waste product release pathways (e.g., urinary tract and GI), clinical monitoring of neo-organ development, and establishing how long it takes to achieve the desired clinical outcome may all need to be established before clinical testing can be considered.

Biosensors and integration of biosensors with TERMPs replacing whole or major portions of an organ's function are becoming a reality. Moving into clinical testing with such products requires definition of *recovery pathways* in the event of product failure; definition of alternative therapies to be used in association with the product if not all organ functions are replaced; understanding TERMP longevity and how to replace the product if the product/neo-organ wears out; and understanding the rate of product failure for proper clinical management.

In spite of these hurdles, the lure of replacing an entire organ is considerable. The benefit to society of replacing a kidney or pancreas is unimaginable. As scientific advances in *in vitro* organ growth are made and regenerative templates for entire organs are pioneered (e.g., through such technologies as organ printing), the potential to replace, regenerate, repair, and restore entire organ systems is being considered. Tissue-engineering approaches may yield solutions for some of the most devastating human conditions, including congenital agenesis, cancer, degenerative disorders, and infectious diseases. However, entry into clinical testing with such products has not yet been defined.

## V. TRANSITION TO CLINICAL TESTING

### Defining and Testing a Prototype

Prior to beginning a clinical testing program, the TERMP's specific characteristics must be defined to the point that the product can be repeatedly and reproducibly manufactured for *in vitro* and *in vivo* testing as defined

earlier. Product characteristics should be sufficiently stable to allow for data-driven demonstration of their clinical utility. Once a prototype is defined, its characteristics are evaluated in a series of tests to define the limits of the initial design criteria that allow for durability testing of the product design by establishing failure points, limits of TERMP application, and the achievement of design criteria.

Anticipating the clinical conditions, complications, and untoward events that may arise during clinical testing also establishes a prototype's potential for clinical utility. A TERMP is seldom introduced as a final functioning neotissue; therefore, characterizing the pharmacological responsiveness, electrophysiological parameters, and phenotypic and structural features of the neotissue or neo-organ that emerges following implantation is key to demonstrating the product's ultimate clinical benefit.

Specific design elements of a final TERMP prototype that will be tested in humans are the culmination of a series of biological, physical, and chemical evaluations obtained during the prototyping phase. This characterization also defines sourcing and control of raw materials, assembly processes (aka: in-process testing) and release criteria. Additionally, the product's shelf life, shipping conditions (temperature, humidity, nutrients, etc.), stability, sterility, and method of use are established before clinical testing. Any unique surgical procedures, clinical management practices during and after implantation, and recovery times are estimated based on the translational medical results using the final prototype product with the fully embodied characteristics.

### Extending Existing Technology

Using previously tested technology platforms can accelerate the entry of any TERMP into clinical testing. Most products are combination products based on multiple technology platforms. Using one or more already-approved scaffold materials, cell-processing methods, culture media components, or transport containers greatly reduces the number of variables that need to be tested in product prototyping and preclinical testing phases. Additionally, historical data available for any technology can help develop testing strategies for a final prototype and even establish early clinical-phase designs.

### Production of TERMPs in GMP Facilities

With established product characteristics, standard operating procedures, and clinical production processes, a GMP-qualified facility can be deployed to manufacture the first clinical prototype. GMP facilities not only meet GMP guidelines, but they have specialized facility designs and highly trained personnel to produce faithfully the first clinical prototypes in a controlled and reproducible fashion. Considerations for GMP facilities include capacity limitations, availability restrictions, and costs to build, operate, and maintain. Furthermore, utilization of a particular GMP

facility may be constrained by the controls needed to generate a particular product. Deploying contract manufacturing is a strategy that can hasten product-prototype production in a manner that complies with regulatory guidelines.

TERMP technologies can vary substantially, so it is not uncommon for small GMP facilities to be custom-built to meet the needs of a particular technology platform. Facility design considerations are outside of the scope of this chapter, but a GMP-qualified facility that can provide the required clean-room processing, shipping, and receiving procedures and HVAC systems for airflow maintenance should be identified before any consideration can be given to initiating clinical testing. This should be done as early as possible, but no later than the final stages of the prototyping phase, to ensure that the necessary facility design capable of producing products in compliance with GTPs and GMPs is available.

Contract manufacturing operations (CMOs) have emerged that produce scaffold-only and scaffold-plus-cell products. These operations have staff skilled in various aspects of product manufacturing and generic facilities that can accommodate a variety of cellular methods and biomaterial-handling needs. A technology transfer plan (Bergmann, 2004) should be established before engaging a CMO, to ensure optimal product generation and the success of the first clinical trial.

### Medical and Market Considerations

Entering clinical testing of TERMPs will not achieve the promise of impacting major unmet medical needs without consideration of market demands. These demands include third-party payers' willingness to support costs, follow-up care, and subsequent patient morbidity. The availability of lower-cost alternatives may be the most significant and practical barrier to clinical testing of a TERMP. Tissue-engineering technologies address medical needs unmet by pharmaceutical agents or devices, but these needs may be met by the modification of medical practices, lower-cost alternatives (e.g., cadaveric skin), or currently accepted medical procedures (e.g., tissue transplantation). Exploratory clinical testing strategies can incorporate these alternative approaches to establish the comparative clinical benefit of a prototype product.

As the science and technology of tissue engineering become more established and regulatory pathways are clarified, products will become more broadly applied. Strengths and limitations of TERMP technologies will determine market size and application to unmet medical needs. At present, products have few competitors in the marketplace, and the opportunities are driven largely by reducing a particular technology to practice.

### Regulatory Considerations and Governance Bodies

Multiple FDA review organizations oversee TERMPs, depending on their characteristics. For device-like products,

CDRH is the regulatory center, for biological products it is CBER, and for combination products, the Office of Combination coordinates a time-bound process that begins with a Request for Designation to assign the combination product to the appropriate center. For example, scaffold and cell TERMPs having a cell-based primary mode of action would most likely be regulated by CBER's Office of Cellular, Tissue and Gene Therapies, with varying involvement from CDRH.

These regulatory organizations conduct evaluations under different regulatory authorities, depending on the designation of the product and the extent of clinical testing required. Lower-risk products that are minimally manipulated and intended for homologous use are considered under Section 361 of the Public Health Services Act and must comply with current good tissue practices (Table 3.6). Higher-risk products (e.g., cartilage that is implanted to provide bladder support) that are modified through tissue culture or genetic manipulation and not intended for homologous use are regulated under Section 351 of the Public Health Service Act and must comply with both the current good tissue practices and good manufacturing practices (Table 3.6) and go through a premarket approval review through an IND/BLA under 21 CFR 312/601 or IDE/PMA 21 CFR 812/814.

In moving toward clinical testing, nongovernmental groups guided by governmental regulations provide oversight of studies conducted in animals and humans. Animal care, use, and housing are governed by an institutional animal care and use committee (IACUC) whose operations are defined and established in 9 CFR 1–3. Although not a direct part of regulatory requirements to engage in clinical testing, institutions conducting animal studies in support of human trial testing are regulated by good laboratory practices (GLPs) and comply with United States Department of Agriculture (USDA) guidelines. Human subject testing is also governed by an institutional review board (IRB). IRB conduct and necessity are controlled by 21 CFR 56 whenever an application is submitted for a research and marketing permit. Specific IRB conduct may vary somewhat between institutions, but the IRB is consulted about necessary preclinical data prior to consideration of human subject testing in that institution.

**Table 3.6. Regulated practices for consideration when taking a TERMP to clinical testing**

VI. ESTABLISHING A REGULATORY PATHWAY

Substantial clarification about appropriate regulatory pathways for evaluating TERMPs has occurred in recent years and is currently most advanced in the United States. Since several regulatory pathways exist for these products and most of the product characteristics consist of a scaffold and cells isolated from a specified source, the Office of Combination Products (OCP) serves as the most common entry point for establishing regulatory authority (21 CFR 3) (FDA, 2003). Notably, some regenerative products may fit into existing regulatory pathways for drugs, devices, or biologics. Since regulatory pathways for individual products are well established, consideration here will focus on TERMPs composed of a combination of materials (biologics, drugs, and/or devices).

A sponsor seeking to obtain regulatory guidance for a combination product prepares a Request for Designation (RFD) document laying out key information requested by the FDA (Table 3.7). This document presents the sponsor's recommendation and rationale for how the combination product should be regulated. The FDA's decision on how to regulate a combination product is based on the primary mode of action, a judgment that focuses on the scaffold and cellular components of the TERMP. If the product is sufficiently close to a product already regulated by a particular center and pathway, the FDA's decision about requirements for clinical trials may mirror that product's regulatory pathway. The FDA has 60 days from the time of RFD submission to render a decision. Once a pathway has been identified, the sponsor can engage that particular reviewing authority for the optimal study plan to support their first clinical trials.

Specific guidance on engaging the Office of Combination Products and establishing communications with the FDA can be found on the FDA website (FDA, updated regularly). Interacting with this office prior to clinical testing can assist in linking to the proper regulatory authority and necessary regulatory guidelines. For some products the primary mode of action is not readily apparent, and the primary mode of action assignment may be based on the most relevant therapeutic activity, intended therapeutic use, similarity of the product to an existing product, or the most relevant safety and efficacy questions. This designation is then used to establish the most relevant regulatory center and potential regulatory pathway for entry into the clinics and ultimate product registration. A current assignment algorithm and flowchart can be obtained on the FDA website.

VIII. ACKNOWLEDGMENTS

VII. CONCLUSIONS

It is inevitable that regenerative medicine-based products will represent an important class of treatments for future patients. These products have the potential to satisfy significant unmet medical needs with an almost unimaginable benefit — a cure, not just a treatment. Regenerative medicine products can be customized to heal the specific needs of the patient in need. Currently, many regenerative medical products have little downside risk, since they eliminate rejection — autologous products representing the clearest example. These products may offer unmatched benefit:risk profiles with the potential to be rapidly approved for introduction into the appropriate patient populations and bring reductions in health care costs and substantial patient benefits, particularly when there are no medically acceptable alternatives.

The path to clinical entry has already been paved for these breakthroughs, which emerge from applying established processes — in cell biology and scaffold engineering — in a knowledgeable way. It is possible that regenerative medical products can be brought to market more rapidly and efficiently than traditional medical products (e.g., pharmaceuticals). The logistical advantages include development that can occur quickly with patient studies (rather than time-consuming and costly large-scale preclinical studies to define unknown risks), smaller trial sizes (customized nature of the products), and long-term follow-up that occurs postregistration (these products, once implanted, become part of the patient). One could easily envisage that once there is a dramatic success that combines effective therapy with compelling clinical data, industrial-scale efforts will open the floodgates to developing treatments for diseases that today fill patients with fear and little hope. The responsibility of tissue engineers for today will be to deliver on the promise of the hope and bring forward the promise of their scientific endeavors.

Department of Defense for its support of the National Tissue Engineering Center through a series of grants.

## Future Perspectives

*Mark E. Furth and Anthony Atala*

- I. Clinical Need
- II. Current State of the Field
- III. Current Challenges

- IV. Future Directions
- V. Future Challenges
- VI. References

### I. CLINICAL NEED

Tissue engineering combines principles of materials and cell transplantation to develop substitute tissues and/or promote endogenous regeneration. The approach initially was conceived to address the critical gap between the growing number of patients on the waiting list for organ transplantation due to end-stage failure and the limited number of donated organs available for such procedures (Lavik and Langer, 2004; Nerem, 2000). Increasingly, tissue engineering and, more broadly, regenerative medicine will focus on even more prevalent conditions in which the restoration of functional tissue would answer a currently unmet medical need. The development of therapies for patients with severe chronic disease affecting major organs such as the heart, kidney, and liver but not yet on transplantation waiting lists would vastly expand the potential impact of tissue-engineering technologies. A notable example is congestive heart failure, with nearly 5 million patients in the United States alone who might benefit from successful engineering of cardiac tissue (Murray-Thomas and Cowie, 2003). Similarly, diabetes mellitus is now recognized as an exploding epidemic, with approximately 16 million patients in the United States and over 217 million worldwide (Smyth and Heron, 2006). Patients with both type 1 and type 2 disease have insufficient pancreatic  $\beta$ -cell mass and potentially could be treated by transplantation of surrogate  $\beta$ -cells or neo-islets (Weir, 2004). A recent report from the U.S. National Academy of Sciences on *Stem Cells and the Future of Regenerative Medicine* highlighted these and other condi-

tions, including osteoporosis (10 million U.S. patients), Alzheimer's and Parkinson's diseases (5.5 million patients), severe burns (0.3 million), spinal cord injuries (0.25 million), and birth defects (0.15 million), as targets of regenerative medicine (Research, 2002).

### II. CURRENT STATE OF THE FIELD

Significant progress has been realized in tissue engineering since its principles were defined (Langer and Vacanti, 1993) and its broad medical and socioeconomic promise were recognized (Lysaght and O'Loughlin, 2000; Vacanti and Langer, 1999). However, to date only a handful of products incorporating cells together with scaffolds, notably bioartificial skin grafts and replacement cartilage, have gained regulatory approval, and these have achieved limited market penetration (Lysaght and Hazlehurst, 2004). Nonetheless, recent clinical reports with multiple years of patient follow-up document the maturation of the field and validate the significance of creating living replacement structures.

In one study, vascular grafts utilizing autologous bone marrow cells seeded onto biodegradable synthetic conduits or patches were implanted into 42 pediatric patients with congenital heart defects (Mastumura *et al.*, 2003; Shin'oka *et al.*, 2005). Safety data were encouraging; there was no evidence of aneurysms or other adverse events after a mean follow-up of 490 days (maximum 32 months) postsurgery. The grafted engineered vessels remained patent and functional and, most importantly, increased in diameter as the patients grew.

Encouraging clinical data also have been reported from work on tissue-engineered bladder constructs. Grafts comprising autologous urothelium and smooth muscle cells expanded *ex vivo* and seeded onto a biodegradable collagen or collagen-PLGA composite scaffold were implanted into seven pediatric patients with high-pressure or poorly compliant bladders in need of cystoplasty (Atala *et al.*, 2006). Serial follow-up data obtained over 22–61 months (mean 46 months) postsurgery provide evidence for the safety and efficacy of the procedure and highlight advantages over previous surgical approaches.

### III. CURRENT CHALLENGES

Technical as well as economic hurdles must be overcome before therapies based on tissue engineering will be able to reach the millions of patients who might benefit from them. One long-recognized challenge is the development of methods to enable engineering of tissues with complex three-dimensional architecture. A particular aspect of this problem is to overcome the mass transport limit by enabling provision of sufficient oxygen and nutrients to engineered tissue prior to vascularization and enhancing the formation of new blood vessels after implantation. The use of angiogenic factors, improved scaffold materials, printing technologies, and accelerated *in vitro* maturation of engineered tissues in bioreactors may help to address this problem. Of particular interest is the invention of novel scaffold materials designed to serve an instructive role in the development of engineered tissues. Methods to prepare improved cell–scaffold constructs by growth in bioreactors before implantation will serve a complementary role in generating more robust clinical products.

A second key challenge centers on a fundamental dichotomy in strategies for sourcing of cells for engineered tissues — the use of autologous cells versus allogeneic or even xenogeneic cells. On the one hand, it appears most cost effective and efficient for manufacturing, regulatory approval, and wide delivery to end users to employ a minimal number of cell donors, unrelated to recipient patients, to generate an off-the-shelf product. On the other hand, grafts can be generated from autologous cells obtained from a biopsy of each individual patient. Such grafts present no risk of immune rejection because of genetic mismatches, thereby avoiding the need for immunosuppressive drug therapy. Thus, the autologous approach, though likely more laborious and costly, appears to have a major advantage. Nonetheless, there are many tissue-engineering applications for which appropriate autologous donor cells may not be available. Therefore, new sources of cells for regenerative medicine are being sought and assessed, mainly from among progenitor and stem cell populations.

### IV. FUTURE DIRECTIONS

#### Smarter Biomaterials

Scaffolds provide mechanical support and shape for neotissue construction *in vitro* and/or through the initial

period after implantation as cells expand, differentiate, and organize (Stock and Vacanti, 2001). Materials that mainly have been used to date to formulate degradable scaffolds include synthetic polymers, such as poly(L-lactic acid) (PLLA) and poly(glycolic acid) (PLGA), and polymeric biomaterials, such as alginate, chitosan, collagen, and fibrin (Langer and Tirrell, 2004). Composites of these synthetic or natural polymers with bioactive ceramics such as hydroxyapatite or certain glasses can be designed to yield materials with a range of strengths and porosities, particularly for the engineering of hard tissues (Boccaccini and Blaker, 2005).

#### Extracellular Matrix

A scaffold used for tissue engineering can be considered an artificial extracellular matrix (ECM) (Rosso *et al.*, 2005). It has long been appreciated that the normal biological ECM, in addition to contributing to mechanical integrity, has important signaling and regulatory functions in the development, maintenance, and regeneration of tissues. ECM components, in synergy with soluble signals provided by growth factors and hormones, participate in the tissue-specific control of gene expression through a variety of transduction mechanisms (Blum *et al.*, 1989; Jones *et al.*, 1993; Juliano and Haskill, 1993; Reid *et al.*, 1981). Furthermore, the ECM is itself a dynamic structure that is actively remodeled by the cells with which it interacts (Behonick and Werb, 2003; Birkedal-Hansen, 1995). An important future area of tissue engineering will be to develop improved scaffolds that more nearly recapitulate the biological properties of authentic ECM (Lutolf and Hubbell, 2005).

Decellularized tissues or organs can serve as sources of biological ECM for tissue engineering. The relatively high degree of evolutionary conservation of many ECM components allows the use of xenogeneic materials (often porcine). Various extracellular matrices have been utilized successfully for tissue engineering in animal models, and products incorporating decellularized heart valves, small intestinal submucosa (SIS), and urinary bladder have received regulatory approval for use in human patients (Gilbert *et al.*, 2006). The use of decellularized matrices is likely to expand, because they retain the complex set of molecules and three-dimensional structure of authentic ECM. Despite many advantages, there are also concerns about the use of decellularized materials. These include the potential for immunogenicity, the possible presence of infectious agents, variability among preparations, and the inability to completely specify and characterize the bioactive components of the material.

#### Electrospinning

Current developments foreshadow the development of a new generation of biomaterials that use defined, purified components to mimic key features of the ECM. Electrospinning allows the production of highly biocompatible micro- and nano-fibrous scaffolds from synthetic materials, such

as poly(epsilon-caprolactone), and from diverse matrix proteins, such as collagen, elastin, fibrinogen, and silk fibroin (Boland *et al.*, 2004; M. Li *et al.*, 2005; W. Li *et al.*, 2003; Matthews *et al.*, 2002; McManus *et al.*, 2006; Pham *et al.*, 2006; Shields *et al.*, 2004). Electrospun protein materials have fiber diameters in the range of those found in native ECM and display improved mechanical properties over hydrogels. The electrospun scaffolds may incorporate additional important ECM components, such as particular subtypes of collagen, glycosaminoglycans, and laminin, either in the spun fibers or as coatings, to promote cell adhesion, growth, and differentiation (Ma *et al.*, 2005; Rho *et al.*, 2006; Zhong *et al.*, 2005). The use of specialized proteins such as silk fibroin offers the opportunities to design scaffolds with enhanced strength or other favorable features (Ayutsede *et al.*, 2006; Jin *et al.*, 2004; Kim *et al.*, 2005; Min *et al.*, 2004), while the use of inexpensive materials such as wheat gluten may enable the production of lower-cost electrospun biomaterials (Woerdeman *et al.*, 2005).

Electrospinning technology also facilitates the production of scaffolds blending proteins with synthetic polymers to confer desired properties. Blending of collagen type I with biodegradable, elastomeric poly(ester urethane)urea generated strong, elastic matrices with improved capacity to promote cell binding and expression of specialized phenotypes as compared to the synthetic polymer alone (W. He *et al.*, 2005; Kwon and Matsuda, 2005; Stankus *et al.*, 2004). Novel properties not normally associated with the ECM may be introduced. For example, nanofibers coelectrospun from polyaniline and gelatin yielded an electrically conductive scaffold with good biocompatibility (M. Li *et al.*, 2006).

One demanding application of scaffold technology is in the production of a biological vascular substitute (Niklason *et al.*, 1999). Electrospun combinations of collagen and elastin or collagen and synthetic polymers have been considered for the development of vascular scaffolds (Boland *et al.*, 2004; W. He *et al.*, 2005; Kwon and Matsuda, 2005; Ma *et al.*, 2005). Recently, electrospinning was utilized to fabricate scaffolds blending collagen type I and elastin with PLGA for use in neo-blood vessels (Stitzel *et al.*, 2006). These scaffolds showed compliance, burst pressure, and mechanics comparable to native vessels and displayed good biocompatibility both *in vitro* and after implantation *in vivo*. When seeded with endothelial and smooth muscle cells, such scaffolds may provide a basis to produce functional vascular grafts suitable for clinical applications such as cardiac bypass procedures.

It may be problematic to introduce cells into a nanofibrillar structure in which pore spaces are considerably smaller than the diameter of a cell (Lutolf and Hubbell, 2005). However, remarkably, it is possible to utilize electrospinning to incorporate living cells into a fibrous matrix. A recent proof-of-concept study documented that smooth muscle cells could be concurrently electrospun with an elastomeric poly(ester urethane)urea, leading to "microintegration" of the cells in strong, flexible fibers with mechani-

cal properties not greatly inferior to those of the synthetic polymer alone (Stankus *et al.*, 2006). The cell population retained high viability, and, when maintained in a perfusion bioreactor, the cellular density in the electrospun fibers doubled over four days in culture. In a similar vein, it has been found that cells can survive inkjet printing (Nakamura *et al.*, 2005; Roth *et al.*, 2004; Xu *et al.*, 2005). Printing of cells together with matrix biomaterials will allow the production of three-dimensional structures that mimic the architectural complexity and cellular distribution of complex tissues. The technology can be applied even to highly specialized, fragile cells, such as neurons. After inkjet printing of hippocampal and cortical neurons, the cells retained their specialized phenotype, as judged by both immunohistochemical staining and whole-cell patch-clamping, a stringent functional test of electrical excitability (Xu *et al.*, 2006). Incorporation of cells by electrospinning or printing generates, in a sense, the ultimate smart biomaterials.

### Smart Polymers

At the chemical level, a number of groups have begun to explore the production of biomaterials that unite the advantages of smart synthetic polymers with the biological activities of proteins. The notion of smart polymers initially described materials that show large conformational changes in response to small environmental stimuli, such as temperature, ionic strength, pH, and light (Galaev and Mattiasson, 1999; Williams, 2005). The responses of the polymer may include precipitation or gelation, reversible adsorption on a surface, collapse of a hydrogel or surface graft, and alternation between hydrophilic and hydrophobic states (A. S. Hoffman *et al.*, 2000). In many cases the change in the state of the polymer is reversible. Biological applications of this technology currently under development span diverse areas, including bioseparation, drug delivery, reusable enzymatic catalysts, molecular switches, biosensors, regulated protein folding, microfluidics, and gene therapy (Roy and Gupta, 2003). In tissue engineering, smart polymers offer promise for revolutionary improvements in scaffolds. Beyond the physical properties of polymers, a major goal is to invest smart biomaterials with specific properties of signaling proteins, such as ECM components and growth factors.

One approach is to link smart polymers to proteins (A. S. Hoffman, 2000; A. S. Hoffman *et al.*, 2000). The proteins can be conjugated either randomly or in a site-specific manner, through engineering of the protein to introduce a reactive amino acid at a particular position. If a conjugation site is introduced near the ligand-binding domain of a protein, induction of a change in conformational state of the smart polymer can serve to regulate the protein's activity (Stayton *et al.*, 1995). This may allow selective capture and recovery of specific cells, delivery of cells to a desired location, and modulation of enzymes, such as matrix metalloproteases, that influence tissue remodeling.

### Proteins and Mimetics

More broadly, the design of genetically modified proteins or of hybrid polymers incorporating peptides and protein domains will enable the creation of a wealth of novel biomaterials that also can be designated smart (Anderson *et al.*, 2004a). These include engineered mutant variants of existing proteins, semisynthetic scaffold materials incorporating protein domains, scaffold materials linked to synthetic peptides, and engineered peptides capable of self-assembly into nanofibers.

Genetic engineering may improve on natural proteins for applications in tissue engineering (van Hest and Tirrell, 2001). For example, a collagen-like protein was generated by using recombinant DNA technology to introduce tandem repeats of the domain of human collagen II most critically associated with the migration of chondrocytes (Ito *et al.*, 2006). When coated onto a PLGA scaffold and seeded with chondrocytes, the engineered collagen was superior to wild-type collagen II in promoting artificial cartilage formation. Similarly, recombinant technology has been employed to generate a series of elastin-mimetic protein triblock copolymers (Nagapudi *et al.*, 2005). These varied broadly in their mechanical and viscoelastic properties, offering substantial choices for the production of novel materials for tissue engineering.

The incorporation of bioactive signals into scaffold materials of the types just described can be accomplished by the chemical linkage of synthetic peptides as tethered ligands. Numerous studies have confirmed that incorporation of the integrin-binding motif arginine-glycine-aspartic acid (RGD), first identified in fibronectin (Ruoslahti and Pierschbacher, 1987), enhances the binding of many types of cells to a variety of synthetic scaffolds and surfaces (Alsberg *et al.*, 2002; Hersel *et al.*, 2003; Liu *et al.*, 2004). The CS5 cell-binding domain of fibronectin (Mould *et al.*, 1991) also has been incorporated into scaffolds and its activity shown to be subject to regulation by sequence context (Heilshorn *et al.*, 2005). It is likely that greater selectivity and potency in cellular binding and enhancement of growth and function will be achieved in the future by taking advantage of the growing understanding of the role of additional binding motifs in addition to and/or in concert with RGD (Salsmann *et al.*, 2006; Takagi, 2004). The integrin family comprises two dozen heterodimeric proteins, so there is great opportunity to expand the set of peptide-binding motifs that could be utilized on tissue-engineering scaffolds, with the hope of achieving greater selectivity and control.

The modification of matrices with bioactive peptides and proteins can extend well beyond binding motifs to promote cell adhesion (Boonthekul and Mooney, 2003). Cells also need to migrate in order to form remodeled tissues. Thus, the rate of degradation of scaffolds used for tissue engineering is a crucial parameter affecting successful regeneration (Alsberg *et al.*, 2003). Regulation of the

degradation rate can be achieved by varying physical parameters of the scaffold. Alternatively, target sites for proteolytic degradation can be built into the scaffold (Halstenberg *et al.*, 2002; S. H. Lee *et al.*, 2005; Mann *et al.*, 2001). For example, the incorporation into a cross-linked synthetic hydrogel of target sequences for matrix metalloproteases known to play an important role in cell invasion was shown to enhance the migration of fibroblasts *in vitro* and the healing of bony defects *in vivo* (Lutolf *et al.*, 2003). Biodegradation of the synthetic matrix was efficiently coupled to tissue regeneration.

### Growth and Angiogenic Factors

Growth factors that drive cell growth and differentiation can be added to the matrix in the form of recombinant proteins or, alternatively, expressed by regenerative cells via gene therapy. Factors of potential importance in tissue engineering and methods to deliver them have been reviewed recently (Vasita and Katti, 2006). Ideally, for optimized tissue formation without risk of hyperplasia, the growth factors should be presented to cells for a limited period of time and in the correct local environment. Biodegradable electrospun scaffolds are capable of releasing growth factors at low rates over periods of weeks to months (Chew *et al.*, 2005; W. He *et al.*, 2005; C. Li *et al.*, 2006). Biologically regulated release of growth factors from scaffolds appears particularly promising as a means to ensure that cells in regenerating neotissues receive these signals when and in the amounts required. For example, by physically entrapping recombinant bone morphogenetic protein-2 (BMP-2) in a hydrogel so that it would be released by matrix metalloproteases, Lutolf *et al.* (2003) achieved excellent bone healing in a critical-size rat calvarial defect model. Similarly, incorporation of a neurotrophic factor in a degradable hydrogel was shown to promote local extension of neurites from explanted retina, and gels were designed to release multiple neurotrophin family members at different rates (Burdick *et al.*, 2006).

Controlled presentation of angiogenic factors such as vascular endothelial growth factor (VEGF) should promote the well-regulated neovascularization of engineered regenerating tissue (Lei *et al.*, 2004; Nomi *et al.*, 2002). Again, it is possible to covalently couple an angiogenic factor to a matrix (Zisch *et al.*, 2001) and to regulate its release based on cellular activity and demand (Zisch *et al.*, 2003). The selection of a sulfated tetrapeptide that mimics the VEGF-binding capability of heparin, a sulfated glycosaminoglycan, provides another potential tool for the construction of scaffolds able to deliver an angiogenic factor to cells in a regulated manner (Maynard and Hubbell, 2005).

Spatial gradients can be generated in the presentation of growth factors within scaffold constructs. This may help to guide the formation of complex tissues and, in particular, to direct migration of cells within developing neotissues (Campbell *et al.*, 2005; DeLong *et al.*, 2005). The introduction of more sophisticated manufacturing technologies,

such as solid free-form fabrication, will allow the production of tissue-engineering constructs comprising scaffolds, incorporated cells, and growth factors in precise, complex three-dimensional structures (Hutmacher *et al.*, 2004).

### Discovery of New Materials

A next stage of smart biomaterials development extends to the design or discovery of bioactive materials not necessarily based directly on naturally occurring carbohydrate or protein structures. At one level this may entail the relatively straightforward chemical synthesis of new materials, coupled with a search for novel activities. By adapting the combinatorial library approach already well established for synthetic peptides and druglike structures, together with even moderately high-throughput assays, thousands of candidate scaffold materials can be generated and tested. Thus, screening of a combinatorial library derived from commercially available monomers in the acrylate family revealed novel synthetic polymers that influenced the attachment, growth, and differentiation of human embryonic stem cells in unexpected ways (Anderson *et al.*, 2004b).

Potentially more revolutionary developments in biomaterials will continue to arise at the interface of tissue engineering with nanotechnology. Basic understanding of the three-dimensional structure of existing biological molecules is being applied to a “bottom-up” approach to generate new, self-assembling supramolecular architectures (Zhang, 2003; Zhao and Zhang, 2004). In particular, self-assembling peptides offer promise because of the large variety of sequences that can be made easily by automated chemical synthesis, the potential for bioactivity, the ability to form nanofibers, and responsiveness to environmental cues (Fairman and Akerfeldt, 2005). Recent advances include the design of short peptides (e.g., heptamers) based on coiled-coil motifs that reversibly assemble into nanofilaments and nanoropes, without excessive aggregation (Wagner *et al.*, 2005). These smart peptide amphiphiles can be induced to self-assemble by changes in concentration, pH, or level of divalent cations (Hartgerink *et al.*, 2001, 2002). Branched structures can be designed to present bioactive sequences such as RGD to cells via nanofiber gels or as coatings on conventional tissue-engineering scaffolds (Guler *et al.*, 2006; Harrington *et al.*, 2006). In addition, assembly can occur under conditions that permit the entrapment of viable cells in the resulting nanofiber matrix (Beniash *et al.*, 2005). The entrapped cells retain motility and the ability to proliferate.

Further opportunities exist to expand the range of peptidic biomaterials by utilizing additional chemical components, such as porphyrins, which can bind to peptides and induce folding (Kovaric *et al.*, 2006). Porphyrins and similar structures also may add functionality, such as oxygen storage, catalysis or photosensitization of chemical reactions, or transfer of charge or molecular excitation energy.

Peptide-based nanofibers may be designed to present bioactive sequences to cells at very high density, substantially exceeding that of corresponding peptide epitopes in biological ECM. For example, a pentapeptide epitope of laminin, isoleucine-lysine-valine-alanine-valine (IKVAV), known to promote neurite extension from neurons, was incorporated into peptide amphiphiles (PA) capable of self-assembly into nanofibers that form highly hydrated (>99.5 weight % water) gels (G. A. Silva *et al.*, 2004). When neural progenitor cells capable of differentiating into neurons or glia were encapsulated during assembly of the nanofibers, they survived over several weeks in culture. Moreover, even without the addition of neurotrophic growth factors, they displayed neuronal differentiation, as exemplified by the extension of large neurites, already obvious after one day, and by expression of  $\beta$ III-tubulin. The production of neuron-like cells from the neural progenitors, whether dissociated or grown as clustered “neurospheres,” was more rapid and robust in the IKVAV-PA gels than on laminin-coated substrates or with soluble IKVAV. By contrast, the production of cells expressing glial fibrillary acidic protein (GFAP), a marker of astrocytic differentiation, was suppressed significantly in the IKVAV-PA gels, even when compared to growth on laminin, which favors neuronal differentiation. The ability to direct stem or progenitor cell differentiation via a chemically synthesized biomaterial, without the need to incorporate growth factors, offers many potential advantages in regenerative medicine.

### Bioreactors

After seeding of cells onto scaffolds, a period of growth *in vitro* is often required prior to implantation. Static cell culture conditions generally have proven suboptimal for the development of engineered neotissues because of limitations on seeding efficiency and transport of nutrients, oxygen, and wastes. Bioreactor systems have been designed to overcome these difficulties and to facilitate the reproducible production of tissue-engineered constructs under tightly controlled conditions. The rapidly developing field of reactors for regenerative medicine applications has been reviewed recently (I. Martin *et al.*, 2004; Portner *et al.*, 2005; Visconti *et al.*, 2006; Wendt *et al.*, 2005). Future advances will likely come through improved understanding of the requirements for tissue development, coupled with increasingly sophisticated reactor engineering.

One area in which basic knowledge must increase is the level of oxygen most appropriate for formation of particular tissues. Contrary to conventional wisdom, for some tissues or cell types it appears that low oxygen tension is important for optimal growth and specialized function. For example, in tissue engineering of cartilage, whereas aerobic conditions are essential for adequate tissue production (Obradovic *et al.*, 1999), cultivation in bioreactors at reduced oxygen tension (e.g., 5% instead of the 20% found in room air) improves the production of glycoasminoglycans and the

expression of additional characteristic phenotypic markers and functions (Kurz *et al.*, 2004; Mizuno and Glowacki, 2005; Saini and Wick, 2004). Growth of stem and progenitor cells at reduced oxygen tension also may enhance the production of differentiated derivatives (Betre *et al.*, 2006; Grayson *et al.*, 2006; D. W. Wang *et al.*, 2005).

It has become increasingly clear that, in addition to regulating mass transport, bioreactors may be used to enhance tissue formation through mechanical stimulation. For example, pulsatile flow helps the maturation of blood vessels (Niklason *et al.*, 1999), while mechanical stretch improves engineered muscle (Barron *et al.*, 2003). Engineering of bone, cartilage, blood vessels, and both skeletal and cardiac muscle all are likely to continue to advance, in part through more sophisticated mechanical conditioning of developing neotissues.

A third area of great importance will be the use of bioreactors to improve the manufacture of engineered grafts for clinical use (I. Martin *et al.*, 2004; Naughton, 2002; Wendt *et al.*, 2005). Key goals will be to standardize production in order to eliminate wasted units, to control costs, and to meet regulatory constraints, including good manufacturing practice (GMP) regulations.

The direct interface between man and bioreactors represents another significant challenge in the bioreactor field. On one hand, the patient is increasingly viewed as a potential *in vivo* bioreactor, providing an optimal environment for cell growth and differentiation to yield neotissues (Warnke *et al.*, 2006). There also are circumstances in which a bioreactor may serve as a bioartificial organ, attached directly to a patient's circulation. The most significant case is the effort to develop a bioartificial liver that can be used to sustain life during acute liver failure, until the patient's endogenous organ regenerates or can be replaced by orthotopic transplantation (Jasmund and Bader, 2002; Sauer *et al.*, 2001, 2003). Most designs to date have focused on the use of hollow-fiber bioreactors seeded either with human hepatic lineage cell lines or xenogeneic (e.g., porcine) hepatocytes. Despite intensive efforts, leading to at least nine clinical trials, no bioartificial liver assist device has yet achieved full regulatory approval (Park and Lee, 2005). However, improved bioreactor systems and the use of primary human hepatocytes show promise for enhanced functionality that may lead to clinical success (Gerlach, 2005; Guthke *et al.*, 2006; Zeilinger *et al.*, 2004).

The creation of a robust bioartificial pancreas to provide a physiologically responsive supply of insulin to diabetes patients represents a comparable major challenge for bioreactor development. Despite three decades of effort, no design has yet proved entirely successful (Kizilel *et al.*, 2005; A. I. Silva *et al.*, 2006), but recent reports offer encouragement (Ikeda *et al.*, 2006; Pileggi *et al.*, 2006). If bioartificial organ technology continues to advance, the demand for new sources of functional human cells such as hepatocytes and pancreatic  $\beta$ -cells will expand dramatically.

## Cell Sources

Both allogeneic and autologous cell sourcing have proven successful in certain tissue-engineering applications. Clinical trials have led to regulatory approval of products based on both types of sources.

Among the approved living, engineered skin products, Dermagraft (Smith & Nephew) and Apligraf (Organogenesis) both utilize allogeneic cells expanded greatly from donated human foreskins to treat many unrelated patients. Despite the genetic mismatch between donor and recipient, the skin cells in Dermagraft and Apligraf do not induce acute immune rejection, possibly because of the absence of antigen-presenting cells in the grafts (Briscoe *et al.*, 1999; Curran and Plosker, 2002; Eaglstein *et al.*, 1999; Horch *et al.*, 2005; Mansbridge, 1998). Thus, these products can be utilized without immunosuppressive drug therapy, which is essential for almost all organ transplantation and would be required for most regenerative-medicine applications using allogeneic cells (Moller *et al.*, 1999). Eventually, the donated skin cells may be rejected, but after sufficient time has passed for the patient's endogenous cells to take their place.

Tissue-engineered products based on autologous cells also have achieved regulatory approval and reached the market. Epicel (Genzyme Biosurgery), a permanent skin replacement product for patients with life-threatening burns, and Carticel (Genzyme Biosurgery), a chondrocyte-based treatment for large articular cartilage lesions, are examples of products based on harvesting and expanding autologous cells.

For some tissue-engineering applications currently under development, such as bladder augmentation, the ability to obtain a tissue biopsy and expand a sufficient number of autologous cells is well established. In other circumstances it is not clear how a patient's own cells could be harvested and/or expanded to yield enough material for production of the needed neotissue or organ. Cardiomyocytes, neurons of the central nervous system, hepatocytes and other liver cells, kidney cells, osteoblasts, and insulin-producing pancreatic beta-cells are examples of differentiated cell types for which new sources could enable novel therapies to address significant unmet medical needs.

Immature precursor cells present within tissue samples are essential for the expansion of cells from biopsies of skin, bladder, or cartilage that enables the engineering of the corresponding neotissues (Bianco and Robey, 2001). The ability to extend tissue engineering to other tissue and organ systems will depend greatly on finding sources of appropriate stem and progenitor cells. Three major sources currently are under intensive investigation by many laboratories: (1) embryonic stem (ES) and embryonic germ (EG) cells derived from discarded human embryos and germ line stem cells, respectively; (2) ES cells created by somatic cell nuclear transfer (therapeutic cloning); and (3) "adult" stem cells from fetal, neonatal, or adult tissue, either autologous or

alogeneic. It appears likely that multiple tissue-engineered products based on each of these sources will be tested in the clinic in the coming years. They pose certain common challenges, and each also has specific drawbacks that must be overcome if clinical use is to be achieved.

### Embryonic Stem Cells

ES cells and EG cells appear very similar and will likely have comparable applications in tissue engineering. In fact, recent evidence suggests that the most closely related *in vivo* cell type to the ES cell is an early germ cell (Zwaka and Thomson, 2005). The ES cells can self-renew, apparently without limit, in culture and are pluripotent — that is, they can give rise to any cell type in the body (Amit *et al.*, 2000; Evans and Kaufman, 1981; G. R. Martin, 1981; Shamblo *et al.*, 1998; Thomson *et al.*, 1998). This great degree of plasticity represents both the strongest attraction and a significant potential limitation to the use of ES cells for regenerative medicine. A major remaining challenge is to direct the efficient production of pure populations of specific desired cell types from human ES cells (Odorico *et al.*, 2001).

ES cells appear unique among normal stem cells in being tumorigenic. Undifferentiated ES cells of murine, nonhuman primate, and human origin form teratomas *in vivo* containing an array of cell types, including representatives of all three embryonic germ layers (Cowan *et al.*, 2004; G. R. Martin, 1981; Thomson *et al.*, 1995, 1998; Vrana *et al.*, 2003). Therefore, it will be important to document rigorously the exclusion of undifferentiated stem cells from any tissue-engineered products derived from ES cells (Lawrenz *et al.*, 2004; Odorico *et al.*, 2001). Strategies have been envisaged to increase safety by introducing into ES cells a suicide gene, for example, that encoding the thymidine kinase of *Herpes simplex* virus, which would render any escaping tumor cells sensitive to the drug ganciclovir (Odorico *et al.*, 2001; Schuldiner *et al.*, 2003). However, the genetic manipulation is itself not without risk, and the need to validate the engineered cell system would likely extend and complicate regulatory review of therapeutic products.

A central issue that must be addressed for tissue-engineered products derived from ES cells, and also from any nonautologous adult stem cells, is immune rejection based on mismatches at genetic histocompatibility loci (Lysaght, 2003). It generally has been assumed that, because human ES cells and their differentiated derivatives can be induced to express high levels of MHC Class I antigens (e.g., HLA-A and HLA-B), any ES cell-based product will be subject to graft rejection (Drukker *et al.*, 2002).

Therapeutic cloning offers a potential means to generate cells with the exact genetic constitution of each individual patient so that immune rejection of grafts based on mismatched histocompatibility antigens should not occur. The approach entails transferring the nucleus of a somatic cell into an enucleated oocyte (SCNT), generating a blastocyst, and then culturing the inner cell mass to obtain an ES

cell line (Colman and Kind, 2000). If required, genetic manipulation of the cells may be carried out to correct an inherited defect prior to production of the therapeutic graft (Rideout *et al.*, 2002). Despite a published claim later withdrawn (Hwang *et al.*, 2005), the generation of human ES cells by SCNT has not yet been achieved. However, the concept of therapeutic cloning to provide cells for tissue-engineering applications has been clearly validated in a large-animal model. Adult bovine fibroblasts were used as nuclear donors and bioengineered tissues were generated from cloned cardiac, skeletal muscle, and kidney cells (Lanza *et al.*, 2002). The grafts, including functioning renal units capable of urine production, were successfully transplanted into the corresponding donor animals long term, with no evidence of rejection. Although SCNT is the subject of political, ethical, and scientific debate, intense efforts in both the private sector and academic institutions are likely to yield cloned human lines in the near future (Hall *et al.*, 2006; Lysaght and Hazlehurst, 2003).

The properties and differentiation potential of a number of human ES cell lines currently used for research were reviewed recently (L. M. Hoffman and Carpenter, 2005). The clinical application of ES cells for tissue engineering will depend on the development of robust methods to isolate and grow them under conditions consistent with good manufacturing practice and regulatory review for safety. In particular, it is important to eliminate the requirement for murine feeder cells by using human feeders or, better, feeder-free conditions. In addition, development of culture conditions without the requirement for nonhuman serum would be advantageous. Progress has been made in the derivation and expansion of human ES cells with human feeder cells (Amit *et al.*, 2003; Hovatta *et al.*, 2003; J. B. Lee *et al.*, 2004, 2005; Miyamoto *et al.*, 2004; Stacey *et al.*, 2006; Stojkovic *et al.*, 2005; Yoo *et al.*, 2005) or entirely without feeders (Amit *et al.*, 2004; Beattie *et al.*, 2005; Carpenter *et al.*, 2004; Cheon *et al.*, 2006; Choo *et al.*, 2006; Darr *et al.*, 2006; Hovatta and Skottman, 2005; Klimanskaya *et al.*, 2005; Rosler *et al.*, 2004; Sjogren-Jansson *et al.*, 2005; G. Wang *et al.*, 2005).

Perhaps the greater challenge remains in directing the differentiation of human ES cells to a given desired lineage with high efficiency. The underlying difficulty is that ES cells are developmentally many steps removed from adult, differentiated cells, and to date we have no general way to deterministically control the key steps in lineage restriction. To induce differentiation *in vitro*, ES cells are allowed to attach to plastic in monolayer culture or, more frequently, to form aggregates called embryoid bodies (Itskovitz-Eldor *et al.*, 2000). Over time within these aggregates cell types of many lineages are generated, including representatives of the three germ layers. The production of embryoid bodies can be enhanced and made more consistent by incubation in bioreactors (Gerecht-Nir *et al.*, 2004). Further selection of specific lineages generally requires sequential exposure to a series of inducing conditions, either based on known

signaling pathways or identified by trial and error. In most cases lineage-specific markers are expressed by the differentiated cells, but cells often do not progress to a full terminally differentiated phenotype. As summarized in recent reviews, the cell lineages that have been generated *in vitro* include, among others, several classes of neurons, astrocytes, oligodendrocytes, multipotent mesenchymal precursor cells, osteoblasts, cardiomyocytes, keratinocytes, pneumocytes, hematopoietic cells, hepatocytes, and pancreatic beta-cells (Caspi and Gepstein, 2006; S. G. Nir *et al.*, 2003; Passier *et al.*, 2006; Priddle *et al.*, 2006; Raikwar *et al.*, 2006; Tian and Kaufman, 2005; Trounson, 2006).

In general, it appears easier to obtain adult cells derived from ectoderm, including neurons, and mesoderm, including cardiomyocytes, than cells derived from endoderm (Trounson, 2006). This may help determine the earliest areas in which ES-derived cells enter clinical translation, once the barriers just discussed are surmounted. Dopaminergic neurons generated from primate and human ES cells already have been tested in animal models of Parkinson's disease, with encouraging results (Perrier *et al.*, 2004; Sanchez-Pernaute *et al.*, 2005; Tabar *et al.*, 2005). Promising data also have been obtained with ES-derived oligodendrocytes in spinal cord injury models (Enzmann *et al.*, 2006; Faulkner and Keirstead, 2005; Keirstead *et al.*, 2005; Mueller *et al.*, 2005; Nistor *et al.*, 2005; Vogel, 2005). Cardiomyocytes derived from human ES cells, similarly, are candidates for future clinical use, although the functional criteria that must be met to ensure physiological competence will be stringent because of the risk of inducing arrhythmias (Caspi and Gepstein, 2004, 2006; Gerecht-Nir and Itskovitz-Eldor, 2004; G. Goh *et al.*, 2005; J. Q. He *et al.*, 2003; Heng *et al.*, 2005; Lev *et al.*, 2005; Liew *et al.*, 2005; Moore *et al.*, 2005; Mummery *et al.*, 2002; S. G. Nir *et al.*, 2003; Passier *et al.*, 2006).

The robust generation of pancreatic  $\beta$ -cells and bioengineered islets from human ES cells or other stem cells would represent a particularly important achievement, with potential to treat diabetes (T. Nir and Dor, 2005; Weir, 2004). Clusters of insulin-positive cells, resembling pancreatic islets and expressing various additional markers of the endocrine pancreatic lineage, have been produced from mouse (Lumelsky *et al.*, 2001; Morioh *et al.*, 2003) and from nonhuman primate and human ES cell lines (Assady *et al.*, 2001; Baharvand *et al.*, 2006; Brolen *et al.*, 2005; Lester *et al.*, 2004). The production of  $\beta$ -like cells can be enhanced by expression of pancreatic transcription factors (Miyazaki *et al.*, 2004; Shiroi *et al.*, 2005). However, the assessment of differentiation must take into account the uptake of insulin from the growth medium, in addition to *de novo* synthesis (Hansson *et al.*, 2004; Paek *et al.*, 2005). It seems fair to conclude that the efficient production of functional  $\beta$ -cells from ES cells remains a difficult objective to achieve. As in other bioengineering applications with ES-derived cells, efforts to reverse diabetes also will depend on the complete

removal of nondifferentiated cells, to avoid the formation of teratoma tumors, which were observed after implantation of ES-derived  $\beta$ -cells in an animal model (Fujikawa *et al.*, 2005).

### Adult Stem Cells

Despite the acknowledged promise of ES cells, the challenges of controlling lineage-specific differentiation and eliminating residual stem cells are likely to extend the timeline for a number of tissue-engineering applications. In many cases adult stem cells may provide a more direct route to clinical translation.

Lineage-restricted stem cells have been isolated from both fetal and postnatal tissues based on selective outgrowth in culture and/or immunoselection for surface markers. Examples with significant potential for new applications in regenerative medicine include neural (Baizabal *et al.*, 2003; E. L. Goh *et al.*, 2003; Leker and McKay, 2004; Rothstein and Snyder, 2004), cardiac (Beltrami *et al.*, 2003; Oh *et al.*, 2003, 2004), muscle-derived (Cao *et al.*, 2005; Deasy *et al.*, 2005; Kuroda *et al.*, 2006; Payne *et al.*, 2005), and hepatic stem cells (Dabeva and Shafritz, 2003; Kamiya *et al.*, 2006; Kubota and Reid, 2000; Schmelzer *et al.*, 2006; Sicklick *et al.*, 2006; Walkup and Gerber, 2006; Zheng and Taniguchi, 2003). A significant feature of each of these populations is a high capacity for self-renewal in culture. Their ability to expand may be less than that for ES cells, but in some cases the cells have been shown to express telomerase and may not be subject to replicative senescence. These adult stem cells are multipotent. Neural stem cells can yield neurons, astrocytes, and oligodendrocytes. Cardiac stem cells are reported to yield cardiomyocytes, smooth muscle, and endothelial cells. Muscle-derived stem cells yield skeletal muscle and can be induced to produce chondrocytes. Hepatic stem cells yield hepatocytes and bile duct epithelial cells. The lineage-restricted adult stem cells all appear nontumorigenic. Thus, unlike ES cells, it is likely that they could be used safely for bioengineered products with or without prior differentiation.

It is possible that some lineage-specific adult stem cells are capable of greater plasticity than might be supposed based solely on their tissue of origin. For example, there is evidence that hepatic stem cells may be induced to generate cells of additional endodermal lineages, such as the endocrine pancreas (Nakajima-Nagata *et al.*, 2004; Yamada *et al.*, 2005; Yang *et al.*, 2002; Zalzman *et al.*, 2005). This type of switching of fates among related cell lineages may prove easier than inducing a full developmental program from a primitive precursor such as an ES cell.

Another class of adult cells with enormous potential value for regenerative medicine is the mesenchymal stem cells (MSC), initially described in bone marrow (Barry and Murphy, 2004; Bruder *et al.*, 1994; Pittenger *et al.*, 1999). These multipotent cells are able to give rise to differentiated cells of connective tissues, including bone, cartilage, muscle,

tendon, and fat. The MSC have, therefore, generated considerable interest for musculoskeletal and vascular tissue engineering (Barry and Murphy, 2004; Gao and Caplan, 2003; Guilak *et al.*, 2004; Pelled *et al.*, 2002; Raghunath *et al.*, 2005; Riha *et al.*, 2005; Risbud and Shapiro, 2005; Tuan *et al.*, 2003). Cells with similar differentiation potential and marker profiles have been isolated from a number of tissues in addition to the bone marrow. A notable source is adipose tissue, in which the cells are abundant and easily obtained by processing of suction-assisted lipectomy (liposuction) specimens (Gimble and Guilak, 2003; Gimble, 2003; Zuk *et al.*, 2001).

In general it seems better to view MSC as mixed populations of progenitor cells with varying degrees of replicative potential, rather than homogeneous stem cells. However, some classes of MSC, including lines cloned from single cells in skin (Bartsch *et al.*, 2005), have been maintained in culture for extended periods. A very small subset of mesenchymal cells from bone marrow, termed MAPC, reportedly are capable of extensive self-renewal and of differentiation into cell lineages not observed with typical MSC, including examples from each embryonic germ layer (Jiang *et al.*, 2002).

Cells originating in a developing fetus and isolated from amniotic fluid or chorionic villi are a new source of stem cells of great potential interest for regenerative medicine (De Coppi *et al.*, 2001; De Coppi *et al.*, 2007; Siddiqui and Atala, 2004; Tsai *et al.*, 2006). Fetal-derived cells with apparently similar properties also have been described in the amnion of term placenta (Miki *et al.*, 2005). Amniotic fluid stem (AFS) cells and amniotic epithelial cells can give rise to differentiated cell types representing the three embryonic germ layers (De Coppi *et al.*, 2007; Miki *et al.*, 2005; Siddiqui and Atala, 2004). Formal proof that single AFS cells can yield this full range of progeny cells was obtained using clones marked by retroviral insertion. The cells can be expanded for well over 200 population doublings, with no sign of telomere shortening or replicative senescence, and retain a normal diploid karyotype. They are readily cultured without need for feeder cells. The AFS cells express some markers in common with embryonic stem cells, such as the surface antigen SSEA4 and the transcription factor Oct3/4, while other markers are shared with mesenchymal and neural stem cells (De Coppi *et al.*, 2007). A broadly multipotent cell population obtained from umbilical cord blood may have certain key properties in common with AFS cells, and it was termed *unrestricted somatic stem cells* (USSCs) (Kogler *et al.*, 2004).

The full developmental potential of the various stem cell populations obtained from fetal and adult sources remains to be determined. It is possible that virtually all of the cell types that might be desired for tissue engineering could be obtained from AFS cells, equivalent stem cells from placenta, USSCs, or comparable populations. Similar approaches to those being taken with ES cells, such as genetic modification with expression vectors for lineage-

specific transcription factors, may help in the generation of differentiated cell types for which it proves difficult to develop a straightforward induction protocol using external signals. However, it will remain necessary to show, beyond induction of a set of characteristic markers, that fully functional mature cells can be generated for any given lineage.

### Immune Compatibility

The growing number of choices of cell sources for bioengineered tissues opens up a range of strategies to obtain the desired cell populations. The issue of immune compatibility remains central. Although lifelong immunosuppression can be successful, as documented by its use in conjunction with orthotopic transplantation to treat terminal organ failure, it would be preferable to design bioengineering-based products that will be tolerated by recipients even without immunosuppressive drugs. The only cell-based therapies guaranteed to be histocompatible would contain autologous cells or those derived by therapeutic cloning (assuming mitochondrial differences are not critical). When a perfectly matched, personalized therapeutic product is not available, there still should be ways to limit the requirement for immunosuppression. First, there may be a strong intrinsic advantage to developing cell-based products from certain stem cells because there is evidence that they, and possibly differentiated cells derived from them, are immune privileged. Second, it may be possible to develop banks of cells that can be used to permit histocompatibility matching with recipient patients.

Human ES cells express low levels of Class I major histocompatibility complex (MHC) antigens (HLA-A, HLA-B) and are negative for MHC Class II (Drukker *et al.*, 2002). Differentiated derivatives of the ES cells remain negative for MHC II but show some increase in MHC Class I that is up-regulated by exposure to interferon. These observations gave rise to the natural assumption that ES cells and their differentiated progeny would be subject to rejection based on MHC mismatches and led to a search for strategies to induce immunological tolerance in recipients of transplanted cells derived from ES lines (Drukker, 2004; Drukker and Benvenisty, 2004). However, it was observed that ES cells in the mouse and similar stage stem cells in the rat could be transplanted successfully in immune-competent animals despite mismatches at the major histocompatibility loci. Furthermore, rodent ES cells may be able to induce immune tolerance in the recipient animals (Fandrich *et al.*, 2002a, 2002b). Even more remarkably, human ES cells and differentiated derivatives were not rejected by immune-competent mice *in vivo*, nor did they stimulate an immune response *in vitro* by human T lymphocytes specific for mismatched MHC. Rather, the human cells appeared to inhibit the T-cell response (L. Li *et al.*, 2004). An independent study using mice with a "humanized" immune system confirmed a very low T-cell response

to human ES cells and differentiated derivatives (Drukker *et al.*, 2006).

MSC from bone marrow and their differentiated derivatives also have been shown both to escape an allogeneic immune response and to possess immunomodulatory activity to block such a response (Aggarwal and Pittenger, 2005; Barry, 2003; Bartholomew *et al.*, 2002; Le Blanc, 2003; Potian *et al.*, 2003). The effect also is observed with MSC isolated from adipose tissue (Puissant *et al.*, 2005). The successful therapeutic use of allogeneic MSC has been confirmed in animal models (Arinzeh *et al.*, 2003; De Kok *et al.*, 2003). Beyond the use of MSC as regenerative cells, it is possible that they could be employed to induce immune tolerance to grafts of other cell types. The mechanisms underlying the immunomodulatory properties of MSC are under active investigation, and understanding them may have profound impact on regenerative medicine (Krampera *et al.*, 2006a, 2006b; Plumas *et al.*, 2005; Sotiropoulou *et al.*, 2006).

Other stem cell populations should be examined for their ability to escape and/or modulate an allogeneic immune response. While it is important to exercise caution in interpreting the laboratory results and in designing clinical trials, there is some reason to hope that the use of allogeneic stem cell-based bioengineered products will not necessarily imply the need for lifelong use of immunosuppressive drugs. In the first FDA-approved clinical trial of allogeneic human neural stem cells, in children with a neural ceroid lipofuscinosis disorder known as Batten disease (Taupin, 2006), immunosuppressive therapy will be utilized for the initial year after cell implantation and then reevaluated.

Banking of stem cells for future therapeutic use extends possibilities both for autologous and allogeneic therapy paradigms, even if it turns out that histocompatibility matching is important for stem cell-based therapies. Amniocentesis specimens, placenta, and cord blood represent sources from which highly multipotent adult stem cells can be obtained and typed with minimal invasiveness. Prospective parents could opt for collection and cryopreservation of such cells for future use by their children in the event of medical need. Furthermore, collection and typing of a sufficient number of samples (ca. 100,000 for the U.S. population) to permit nearly perfect histocompatibility matching between unrelated donors and recipients would be readily achieved. Similarly, collection and banking of cells from adult adipose tissue appears straightforward. Although it would entail a greater level of effort and could be politically

controversial, it also might be feasible to prepare and bank a relatively large set of human ES lines to facilitate histocompatibility matching. One recent study suggests that a surprisingly modest number of banked lines or specimens could provide substantial ability to match donor cells to recipients (Taylor *et al.*, 2005). Based on patients registered on a kidney transplant waiting list in the United Kingdom, the authors concluded that “Approximately 150 consecutive blood group-compatible donors, 100 consecutive blood group O donors, or 10 highly selected homozygous donors could provide the maximum practical benefit for HLA matching.” The main criterion in this analysis was achieving at least an HLA-DR match. However, the possibility to select a small number of donors (ca. 10) homozygous for common HLA types from a pool of approximately 10,000 potential donors would allow complete matching for over one-third of patients and beneficial matching (one HLA-A or one HLA-B mismatch only) for two-thirds, at least for a relatively genetically homogeneous population. Taken together with the low immunogenicity of certain stem cells, these results support the concept that the use of allogeneic bioengineered products may not demand concomitant intensive immunosuppressive treatment.

## V. FUTURE CHALLENGES

The clinical application of tissue engineering lies largely ahead of us. Although a handful of products have achieved regulatory approval and entered the marketplace, many more are in the planning or proof-of-concept stage. In order to reach the large number of patients who might potentially benefit from bioengineered therapeutics, advances will be required in manufacturing and distributing complex products. This will be a fruitful area for engineers to address.

It also will be critical to develop a close partnership among academic and industrial scientists and the regulatory agencies (e.g., the U.S. Food and Drug Administration) that must assess new therapies for safety and efficacy. Products that may contain novel cellular components, biomaterials, and active growth or angiogenic factors will demand sophisticated, multifaceted review. Historically, regulatory agencies have had far greater experience with single drug entities or devices than with combination products. However, there is reason for optimism that the FDA’s experiences to date with successful applications will pave the way to effective review of future bioengineered products.

## I. INTRODUCTION

This chapter is a general introduction to the properties of animal or human cells. It deals with gene expression, metabolism, protein synthesis and secretion, membrane properties, response to extracellular factors, cell division, properties of the cytoskeleton, cell adhesion, and the extracellular matrix. It shows how these cellular properties underlie the specific conditions required for successful tissue culture. In particular cells require effective access to nutrients, removal of waste products, and their growth and behavior are controlled by a variety of extracellular hormones and growth factors present in the medium. The properties of individual cells are also the basis for understanding how cells can become organized into tissues, which are normally composed of more than one cell type and have a specific microarchitecture appropriate to their function.

To a naive observer the term *tissue engineering* might seem a contradiction. The word *engineering* conjures up a vision of making objects from hard components, such as metals, plastics, concrete, and silicon, that are mechanically robust and will withstand a range of environmental conditions. The components themselves are often relatively simple, and the complexity of a system emerges from the number and connectivity of the parts. By contrast, the cells of living organisms are themselves highly delicate and highly complex. Despite our knowledge of a vast amount of molecular biological detail concerning cell structure and function, their properties are still understood only in qualitative

terms, and so any application using cells involves a lot of craft skill as well as rational design. What follows is a very brief account of cell properties intended for newcomers to tissue engineering who have an engineering or physical science background. It is intended to alert readers to some of the issues involved in working with cells and to pave the way for understanding how cells form tissues and organs, topics dealt with in more detail in the later chapters. Because it comprises very general material, it is not specifically referenced, although some further reading is provided at the end.

Cells are the basic building blocks of living organisms, in the sense that they can survive in isolation. Some organisms, such as bacteria, protozoa, and many algae, actually consist of single free-living cells. But most cells are constituents of multicellular organisms, which, though they can survive in isolation, need very carefully controlled conditions to do so. A typical animal cell suspended in liquid will be a sphere of the order of about 20 microns in diameter (Fig. 5.1).

Most cells will not grow well in suspension, and so they are usually grown attached to a substrate, where they flatten and may be quite large in horizontal dimensions but only a few microns in vertical dimension. All eukaryotic cells contain a *nucleus*, in which is located the genetic material that ultimately controls everything the cell is composed of and all the activities it carries out. This is surrounded by *cytoplasm*, which has a very complex structure and contain

**FIG. 5.1.** Structure of a generalized animal cell. (From paternityexperts.com website.)

substructures called *organelles* that are devoted to specific biochemical functions. The outer surface of the cell is the *plasma membrane*, which is of crucial importance as the frontier across which all materials must pass on their way in or out. The complexity of a single cell is awesome, since it will contain thousands of different types of protein molecules, arranged in many very complex, multimolecular aggregates comprising both hydrophobic and aqueous phases, and also many thousands of low-molecular-weight metabolites, including sugars, amino acids, nucleotides, fatty acids, and phospholipids, among many others. Although some individual steps of metabolism may be near to thermodynamic equilibrium, the cell as a whole is very far from equilibrium and is maintained in this condition by a continuous interchange of substances with the environment. Nutrients are chemically transformed, with release of energy that is used to maintain the structure of the cell and to synthesize the tens of thousands of different macromolecules on which its continued existence depends. Maintaining cells in a healthy state means to provide them continuously with all the substances they need, in the right overall environment of substrate, temperature, and osmolarity, and also continuously to remove all potentially toxic waste products.

## II. THE CELL NUCLEUS

The nucleus contains the genes that control the life of the cell. A *gene* is a sequence of DNA that codes for a protein,

or for a nontranslated RNA, and it is usually considered also to include the associated regulatory sequences as well as the coding region itself. The vast majority of eukaryotic genes are located in the nuclear chromosomes, although a few genes are also carried in the DNA of mitochondria and chloroplasts. The genes encoding nontranslated RNAs include those for ribosomal (transfer) RNAs and also a large number of microRNAs that are probably involved in controlling expression of protein-coding genes. The total number of protein-coding genes in vertebrate animals is about 30,000, and every nucleus contains all the genes, irreversible DNA modifications being confined to cells of the immune system in respect of the genes encoding antibodies and T-cell receptors.

The DNA is complexed into a higher-order structure called *chromatin* by the binding of basic proteins called *histones*. Protein-coding genes are transcribed into messenger RNA (mRNA) by the enzyme RNA polymerase II. Transcription commences at a transcription start sequence and finishes at a transcription termination sequence. Genes are usually divided into several *exons*, each of which codes for a part of the mature mRNA. The primary RNA transcript is extensively processed before it moves from the nucleus to the cytoplasm. It acquires a “cap” of methyl guanosine at the 5′ end and a polyA tail at the 3′ end both of which stabilize the message by protecting it from attack by exonucleases. The DNA sequences in between the exons are called *introns*, and the portions of the initial transcript complementary to

**FIG. 5.2.** (a) Structure of a typical gene. (b) Operation of a transcription factor. (From Slack, 2005.)

the introns are removed by splicing reactions catalyzed by *snRNPs* (small nuclear ribonucleoprotein particles). It is possible for the same gene to produce several different mRNAs as a result of alternative splicing, whereby different combinations of exons are spliced together from the primary transcript. In the cytoplasm the mature mRNA is translated into a polypeptide by the ribosomes. The mRNA still contains a 5' leader sequence and a 3' untranslated sequence flanking the protein-coding region, and these untranslated regions may contain specific sequences responsible for translational control or intracellular localization.

### Control of Gene Expression

There are many genes whose products are required in all tissues at all times, for example, those concerned with basic cell structure, protein synthesis, or metabolism. These are referred to as *housekeeping* genes. But there are many others whose products are specific to particular cell types, and indeed the various cell types differ from each other *because* they contain different repertoires of proteins. This means that the control of gene expression is central to tissue engineering. Control may be exerted at several points. Most common is control of *transcription*, and we often speak of genes being “on” or “off” in particular situations, meaning that they are or are not being transcribed. There are also many examples of *translational regulation*, where the mRNA exists in the cytoplasm but is not translated into protein until some condition is satisfied. Control may also be exerted at the stage of nuclear RNA processing or indirectly via the stability of individual mRNAs or proteins.

Control of transcription depends on regulatory sequences within the DNA and on proteins called *transcription factors* that interact with these sequences. The promoter region of a gene is the region just upstream from the transcription start site to which the RNA polymerase binds. The RNA polymerase is accompanied by a set of general transcription factors, which together make up a *transcription complex*. In addition to the general factors required for the assembly of the complex, there are numerous specific transcription factors that bind to specific regulatory sequences that may be either adjacent to or at some distance from the promoter (Fig. 5.2).

### Transcription Factors

Transcription factors are the proteins that regulate transcription. They usually contain a DNA-binding domain and a regulatory domain, which will either activate or repress transcription. Looping of the DNA may bring these regulatory domains into contact with the transcription complex and either promotes or inhibits its activity. There are many families of transcription factors, classified by the type of DNA-binding domain they contain, such as the homeodomain and the zinc-finger domain. Most are nuclear proteins, although some exist in the cytoplasm until they are activated and then enter the nucleus. Activation often occurs in response to intercellular signaling (see later). One type of transcription factor, the nuclear receptor family, is directly activated by lipid-soluble signaling molecules, such as retinoic acid and glucocorticoids.

Each type of DNA-binding domain in a protein has a corresponding type of target sequence in the DNA, usually 20 nucleotides or less. The activation domains of transcription factors often contain many acidic amino acids making up an *acid blob*, which accelerates the formation of the general transcription complex. Some transcription factors recruit histone acetylases, which open up the chromatin by neutralizing amino groups on the histones by acetylation and allow access of other proteins to the DNA. Although it is normal to classify transcription factors as activators or repressors of transcription, their action is also sensitive to context, and the presence of other factors may on occasion cause an activator to function as a repressor, or vice versa.

### Other Controls of Gene Activity

Some aspects of gene control are of a more stable and longer-term character than that exerted by combinations of positive and negative transcription factors. To some extent this depends on the remodeling of the chromatin structure, which is still poorly understood. The chromosomal DNA is complexed with histones into nucleosomes and is coiled into a 30-nm-diameter filament, which is in turn arranged into higher-order structures. In much of the genome the nucleosomes are to some extent mobile, allowing access of transcription factors to the DNA. This type of chromatin is called *euchromatin*. In other regions the chromatin is highly condensed and inactive, then being called *heterochromatin*. In the extreme case of the nucleated red blood cells of nonmammalian vertebrates, the entire genome is heterochromatic and inactive. Chromatin structure is regulated to some degree by protein complexes (such as the well-known polycomb and trithorax groups), which affect the expression of many genes but are not themselves transcription factors.

An important element of the chromatin remodeling is the control through acetylation of lysines on the exposed N-termini of histones. This partially neutralizes the binding of the histones to the negatively charged phosphodiester chains of DNA and thus opens up the chromatin structure and enables transcription complexes to assemble on the DNA. The degree of histone acetylation is controlled, at least partly, by DNA methylation, because histone deacetylases are recruited to methylated regions and will tend to inhibit gene activity in these regions. DNA methylation occurs on cytosine residues in CG sequences of DNA. Because CG on one strand will pair with GC on the other, antiparallel, strand, potential methylation sites always lie opposite one another on the two strands. There are several DNA methyltransferase enzymes, including *de novo* methylases, which methylate previously unmethylated CGs, and maintenance methylases, which methylate the other CG of sites bearing a methyl group on only one strand. Once a site is methylated, it will be preserved through subsequent rounds of DNA replication, because the hemimethylated site resulting

from replication will be a substrate for the maintenance methylase.

There are many other chemical modifications of the histones in addition to acetylation, and it is probable that these too can be retained on chromosomes when the DNA is replicated. So both DNA methylation and histone modifications provide means for maintaining the state of activity of genes in differentiated cells, even after the original signals for activation or repression have disappeared.

## III. THE CYTOPLASM

The cytoplasm consists partly of proteins in free solution, although it also possesses a good deal of structure, which can be visualized as the cytoskeleton (see later). Generally considered to be in free solution, although probably in macromolecular aggregates, are the enzymes that carry out the central metabolic pathways. In particular, the pathway called *glycolysis* leads to the degradation of glucose to pyruvate. Glucose is an important metabolic fuel for most cells. Mammalian blood glucose is tightly regulated around 5–6 mM, and glucose is a component of most tissue culture media. Glycolysis leads to the production of two molecules of ATP per molecule of glucose, with a further 36 molecules of ATP produced by oxidative phosphorylation, which is needed for a very wide variety of synthetic and maintenance activities.

The cytoplasm contains many types of *organelles*, which are structures composed of phospholipid bilayers. *Phospholipids* are molecules with a polar head group and a hydrophobic tail. They tend to aggregate to form sheets in which all the head groups are exposed on the surface and the hydrophobic tails associate with each other to form a hydrophobic phase. Most cell organelles are composed of membranes comprising two sheets of phospholipid molecules with their hydrophobic faces joined. The mitochondria are the organelles responsible for oxidative metabolism as well as for other metabolic processes, such as the synthesis of urea. They are composed of an outer and an inner phospholipid bilayer. The oxidative degradation of sugars, amino acids, and fatty acids is accompanied by the production of ATP. Pyruvate produced by glycolysis is converted to acetyl CoA, and this is oxidized to two molecules of CO<sub>2</sub> by the citric acid cycle, with associated production of 12 molecules of ATP in the electron transport chain of the mitochondria. Because of the importance of oxidative metabolism for ATP generation, cells need oxygen to support themselves.

Tissue culture cells are usually grown in atmospheric oxygen concentration (about 20% by volume), although the optimum concentration may be somewhat lower than this since the oxygen level within an animal body is often lower than in the external atmosphere. Too much oxygen can be deleterious because it leads to the formation of free radicals, which cause damage to cells. Tissue culture systems may therefore be run at lower oxygen levels, such as 5%. The

oxidation of pyruvate and acetyl CoA also results in the production of  $\text{CO}_2$ , which needs to be removed continuously to avoid acidification.

Apart from the central metabolic pathways, the cell is also engaged in the continuous synthesis and degradation of a wide variety of lipids, amino acids, and nucleotides.

The cytoplasm contains the *endoplasmic reticulum*, which is a ramifying system of phospholipid membranes. The interior of the endoplasmic reticulum can communicate with the exterior medium through the exchange of membrane vesicles with the plasma membrane. Proteins that are secreted from cells or that come to lie within the plasma membrane are synthesized by ribosomes that lie on the cytoplasmic surface of the endoplasmic reticulum, and the products are passed through pores into the endoplasmic reticulum lumen. From here they move to the *Golgi apparatus*, which is another collection of internal membranes, in which carbohydrate chains are often added. From there they move to the cell surface or the exterior medium. Secretion of materials is a very important function of all cells, and it needs to be remembered that their environment in tissue culture depends not only on the composition of the medium provided but also on what the cells themselves have been making and secreting.

The intracellular proteins are synthesized by ribosomes in the soluble cytoplasm. There is a continuous production of new protein molecules, the composition depending on the repertoire of gene expression of the cell. There is also a continuous degradation of old protein molecules, mostly in a specialized structure called the *proteosome*. This continuous turnover of protein requires a lot of ATP.

### The Cell Surface

The plasma membrane is the frontier between the cell and its surroundings. It is a phospholipid bilayer incorporating many specialized proteins. Very few substances are able to enter and leave cells by simple diffusion, in fact this method is really only available to low-molecular-weight hydrophobic molecules such as retinoic acid, steroids, and thyroid hormones. The movement of inorganic ions across the membrane is very tightly controlled. The main control is exerted by a sodium–potassium exchanger, which expels sodium and concentrates potassium. Differential back-diffusion of these ions then generates an electric potential difference across the membrane that ranges from about 10 mV in red blood cells to 80–90 mV (negative inside) in excitable cells such as neurons. Calcium ions are very biologically active within the cell and are normally kept at a very low intracellular concentration, about  $10^{-7}$  M. This is about  $10^4$  times lower than the typical exterior concentration, which means that any damage to the plasma membrane is likely to let in a large amount of calcium, which will damage the cell beyond repair. The proteins of the plasma membrane may be very hydrophobic molecules entirely contained within the lipid phase, but more usually they

have hydrophilic regions projecting to the cell exterior or to the interior cytoplasm or both. These proteins have a huge range of essential functions. Some are responsible for anchoring cells to the substrate or to other cells through adhesion molecules and junctional complexes. Others are responsible for transporting molecules across the plasma membrane. These include ion transporters and carriers for a large range of nutrients. Then there are the receptors for extracellular signaling molecules, which are critical for controlling cellular properties and behavior. These include hormones, neurotransmitters, and growth factors. Some receptors serve as ion channels, for example, admitting a small amount of calcium when stimulated by their specific ligand. Other receptors are enzymes and initiate a metabolic cascade of intracellular reactions when stimulated. These reaction pathways often involve protein phosphorylation and frequently result in the activation of a transcription factor and thereby the activation of specific target genes. The repertoire of responses that a cell can show depends on which receptors it possesses, how these are coupled to signal transduction pathways, and how these pathways are coupled to gene regulation. The serum that is usually included in tissue culture media contains a wide range of hormones and growth factors and is likely to stimulate many of the cell surface receptors.

### Signal Transduction

Lipid-soluble molecules, such as steroid hormones, can enter cells by simple diffusion. Their receptors are multi-domain molecules that also function as transcription factors. Binding of the ligand causes translocation to the nucleus, where the receptor complex can activate its target genes (Fig. 5.3a).

Most signalling molecules are proteins, which cannot diffuse across the plasma membrane and so work by binding to specific cell surface receptors. There are three main classes of these: enzyme-linked receptors, G-protein-linked receptors, and ion channel receptors. Enzyme-linked receptors are often tyrosine kinases or Ser/Thr kinases (Fig. 5.3b). All have a ligand-binding domain on the exterior of the cell, a single transmembrane domain, and the enzyme active site on the cytoplasmic domain. For receptor tyrosine kinases, the ligand binding brings about dimerization of the receptor, which results in an autophosphorylation whereby each receptor molecule phosphorylates and activates the other. The phosphorylated receptors can then activate a variety of targets. Many of these are transcription factors that are activated by phosphorylation and move to the nucleus, where they activate their target genes. In other cases, a cascade of kinases activate each other down the chain, culminating in the activation of a transcription factor. Roughly speaking, each class of factors has its own associated receptors and a specific signal transduction pathway; however, different receptors may be linked to the same signal transduction pathway, or one receptor may feed into more than one

**FIG. 5.3.** Different types of signal transduction. (From Slack, 2005.)

pathway. The effect of one pathway on the others is often called *cross-talk*. The significance of cross-talk can be hard to assess from biochemical analysis alone, but is much easier to assess using genetic experiments in which individual components are mutated to inactivity and the overall effect on the cellular behavior can be assessed.

There are several classes of G-protein-linked receptors (Fig. 5.3c). The best known are seven-pass membrane proteins, meaning that they are composed of a single polypeptide chain crossing the membrane seven times. These are associated with trimeric G proteins composed of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits. When the ligand binds, the activated receptor causes exchange of guanosine diphosphate (GDP) bound to the  $\alpha$  subunit for guanosine triphosphate (GTP); the activated  $\alpha$  subunit is released and can interact with other membrane components. The most common target is adenylyl cyclase, which converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (AMP). Cyclic AMP activates protein kinase A (PKA), which phosphorylates various further target molecules affecting both intracellular metabolism and gene expression.

Another large group of G-protein-linked receptors uses a different trimeric G protein to activate the inositol phospholipid pathway (Fig. 5.3c). Here the G protein activates phospholipase C  $\beta$ , which breaks down phosphatidylinositol bisphosphate ( $\text{PIP}_2$ ) to diacylglycerol (DAG) and inositol trisphosphate ( $\text{IP}_3$ ). The DAG activates an important membrane-bound kinase, protein kinase C. Like protein kinase A, this has a large variety of possible targets in different contexts and can cause both metabolic responses and changes in gene expression. The  $\text{IP}_3$  binds to an  $\text{IP}_3$  receptor ( $\text{IP}_3\text{R}$ ) in the endoplasmic reticulum and opens calcium channels, which admit calcium ions into the cytoplasm. Normally cytoplasmic calcium is kept at a very low concentration of around  $10^{-7}$  M. An increase caused either by opening of an ion channel in the plasma membrane or as a result of  $\text{IP}_3$  action can again have a wide range of effects on diverse target molecules.

Ion channel receptors (Fig. 5.3d) are also very important. They open on stimulation to allow passage of Na, K, Cl, or Ca ions. Na and K ions are critical to the electrical excitability of nerve or muscle. As mentioned earlier, Ca ions are very potent and can have a variety of effects on cell structure at low concentration.

## IV. GROWTH AND DEATH

Tissue engineering inevitably involves the growth of cells in culture, so the essentials of cell multiplication need to be understood. A typical animal cell cycle is shown in Fig. 5.4, and some typical patterns of cell division are shown in Fig. 5.5. The cell cycle is conventionally described as consisting of four phases. M indicates the phase of mitosis, S indicates the phase of DNA replication, and G1 and G2 are the intervening phases. For growing cells, the increase in mass is continuous around the cycle, and so is the synthesis of most of the cell's proteins. Normally the cell cycle is coordinated with the growth of mass. If it were not, cells would increase or decrease in size with each division. There are various internal controls built into the cycle, for example, to ensure that mitosis does not start before DNA replication is completed. These controls operate at checkpoints around

**FIG. 5.4.** The cell cycle, with phases of growth, DNA replication, and division. (From Slack, 2005.)

the cycle at which the process stops unless the appropriate conditions are fulfilled.

Control of the cell cycle depends on a metabolic oscillator comprising a number of proteins called *cyclins* and a number of cyclin-dependent protein kinases (Cdks). In order to pass the M checkpoint and enter mitosis, a complex of cyclin and Cdk (called M-phase promoting factor, MPF) has to be activated. This phosphorylates and thereby activates the various components required for mitosis (nuclear breakdown, spindle formation, chromosome condensation). Exit from M phase requires the inactivation of MPF, via the destruction of cyclin, so by the end of the M phase it has disappeared. Passage of the G1 checkpoint depends on a similar process operated by a different set of cyclins and Cdks, whose active complexes phosphorylate and activate the enzymes of DNA replication. This is also the point at which the cell size is assessed. The cell cycle of the G1, S, G2, and M phases is universal, although there are some modifications in special circumstances. The rapid-cleavage cycles of early development have short or absent G1 and G2 phases, and there is no size check, the cells halving in volume with each division. The meiotic cycles require the same active MPF complex to get through the two nuclear divisions, but there is no S phase in between.

In the mature organism most cells are quiescent unless they are stimulated by growth factors. In the absence of growth factors, cells enter a state called G0, in which the Cdks and cyclins are absent. Restitution of growth factors induces the resynthesis of these proteins and the resump-

**FIG. 5.5.** Types of cell division. (a) Cleavage as found in early embryos. (b) Asymmetrical division, also found in early embryos. (c) Exponential growth found in tissue culture. (d) Stem cell division, found in renewal tissues in animals. (From Slack, 2005.)

tion of the cycle, starting from the G1 checkpoint. One factor maintaining the G0 state is a protein called Rb (retinoblastoma protein). This becomes phosphorylated, and hence deactivated, in the presence of growth factors. In the absence of Rb, a transcription factor called E2F becomes active and initiates a cascade of gene expression culminating in the resynthesis of cyclins, Cdks, and other components needed to initiate the S phase.

Cells often have the capability for exponential growth in tissue culture (Fig. 5.5c), but this is very rarely found in animals. Although some differentiated cell types can go on dividing, there is a general tendency for differentiation to be accompanied by a slowdown or cessation of division. In postembryonic life, most cell division is found among stem cells and their immediate progeny, called *transit amplifying cells*. Stem cells are cells that can both reproduce themselves and generate differentiated progeny for their particular tissue type (Fig. 5.5d). This does not necessarily mean that

every division of a stem cell has to be an asymmetrical one, but over a period of time half the progeny will go to renewal and half to differentiation. The term *stem cell* is also used for embryonic stem cells (ES cells) of early mammalian embryos. These are early embryo-type cells that can be grown in culture and are capable of repopulating embryos and contributing to all tissue types.

Asymmetric cell divisions necessarily involve the segregation of different cytoplasmic determinants to the two daughter cells, evoking different patterns of gene activity in their nuclei and thus bringing about different pathways of development. The nature of determinants is still poorly understood but often involves autosegregation of a self-organizing protein complex called the PAR complex.

Some tissues are formed by growth and differentiation of cells in the embryo but are quiescent in the adult organism. These include neurons and muscle. In fact there is now known to be some limited production of new neurons in the brain from stem cells and of new muscle fibers from muscle satellite cells. Some tissues are capable of expansion but remain quiescent most of the time unless stimulated by damage or hormonal stimulation. These would include most of the glandular-type tissues, such as the liver, kidney, and pancreas. Some tissues are in a state of continuous renewal, with a proliferative zone containing stem cells constantly dividing and generating new progeny that differentiate and then die. These include the haematopoietic system in the bone marrow, which forms all cells of the blood and immune system. It also includes the epithelial lining of the gut and the epidermis of the skin.

## V. CYTOSKELETON

The cytoskeleton is important for three distinct reasons. First, the orientation of cell division may be important. Second, animal cells move around a lot, either as individuals or as part of moving cell sheets. Third, the shape of cells is an essential part of their ability to carry out their functions. All of these activities are functions of the cytoskeleton.

The three main components of the cytoskeleton are:

- microfilaments, made of actin
- microtubules, made of tubulin
- intermediate filaments, made of cytokeratins in epithelial cells, vimentin in mesenchymal cells, neurofilament proteins in neurons, and glial fibrillary acidic protein (GFAP) in glial cells

Microtubules and microfilaments are universal constituents of eukaryotic cells, while intermediate filaments are found only in animals.

### Microtubules

Microtubules (Fig. 5.6) are hollow tubes of 25-nm diameter composed of tubulin. Tubulin is a generic name for a family of globular proteins that exist in solution as heterodimers of  $\alpha$ - and  $\beta$ -type subunits, and they are one of the more

**FIG. 5.6.** Microtubules. (a) Arrangement in cell. (b) The GTP cap. (c) Motor proteins move along the tubules. (d) Structure of the cell division spindle. (From Slack, 2005.)

abundant cytoplasmic proteins. The microtubules are polarized structures, with a minus end anchored to the centrosome and a free plus end, at which tubulin monomers are added or removed. Microtubules are not contractile but exert their effects through length changes based on polymerization and depolymerization. They are very dynamic, either growing by addition of tubulin monomers or retracting by loss of monomers, and individual tubules can grow and shrink over a few minutes. The monomers contain GTP bound to the  $\beta$  subunit, and in a growing plus end this stabilizes the tubule. But if the rate of growth slows down, hydrolysis of GTP to GDP will catch up with the addition of monomers. The conversion of bound GTP to GDP renders the plus end of the tubule unstable, and it will then start to depolymerize. The drugs colchicine and colcemid bind to monomeric tubulin and prevent polymerization. Among other effects this causes the disassembly of the mitotic spindle. These drugs cause cells to become arrested in mitosis and are often used in studies of cell kinetics.

The shape and polarity of cells can be controlled by locating capping proteins in particular parts of the cell cortex that bind the free plus ends of the microtubules and stabilize them. The positioning of structures within the cell also depends largely on microtubules. There exist special

**FIG. 5.7.** Microfilaments. (a) Arrangement in cell. (b) Role in cell division. (c) Contraction achieved by movement of myosin along microfilament. (From Slack, 2005.)

motor proteins that can move along the tubules, powered by hydrolysis of ATP, and thereby can transport other molecules to particular locations within the cell. The kinesins move toward the plus ends of the tubules, while the dyneins move toward the minus ends.

Microtubules are prominent during cell division. The minus ends of the tubules originate in the centrosome, which is a microtubule-organizing center able to initiate the assembly of new tubules. In mitotic prophase the centrosome divides, and each of the radiating sets of microtubules becomes known as an *aster*. The two asters move to the opposite sides of the nucleus to become the two poles of the *mitotic spindle*. The spindle contains two types of microtubules. The *polar* microtubules meet each other near the center and become linked by plus-directed motor proteins. These tend to drive the poles apart. Each chromosome has a special site, called a *kinetochore*, that binds another group of microtubules, called *kinetochore* microtubules. At anaphase the kinetochores of homologous chromosomes separate. The polar microtubules continue to elongate, while the kinetochore microtubules shorten by loss of tubulin from both ends and draw the chromosome sets into the opposite poles of the spindle.

### Microfilaments

Microfilaments (Fig. 5.7) are polymers of actin, which is the most abundant protein in most animal cells. In vertebrates there are several different gene products, of which  $\alpha$  actin is found in muscle and  $\beta/\gamma$  actins in the cytoskeleton of nonmuscle cells. For all actin types the monomeric soluble form is called G-actin. Actin filaments have an inert

minus end and a growing plus end to which new monomers are added. G-actin contains ATP, and this becomes hydrolyzed to ADP shortly after addition to the filament. As with tubules, a rapidly growing filament will bear an ATP cap that stabilizes the plus end. Microfilaments are often found to undergo *treadmilling*, such that monomers are continuously added to the plus end and removed from the minus end while leaving the filament at the same overall length. Microfilament polymerization is prevented by a group of drugs called *cytochalasins*, and existing filaments are stabilized by another group, called *phalloidins*. Like microtubules, microfilaments have associated motor proteins that will actively migrate along the fiber. The most abundant of these is myosin II, which moves toward the plus end of microfilaments, the process being driven by the hydrolysis of ATP. To bring about contraction of a filament bundle, the myosin is assembled as short bipolar filaments with motile centers at both ends. If neighboring actin filaments are arranged with opposite orientation, then the motor activity of the myosin will draw the filaments past each other, leading to a contraction of the filament bundle.

Microfilaments can be arranged in various different ways, depending on the nature of the accessory proteins with which they are associated. Contractile assemblies contain microfilaments in antiparallel orientation associated with myosin. These are found in the *contractile ring*, which is responsible for cell division, and in the *stress fibers*, by which fibroblasts exert traction on their substratum. Parallel bundles are found in filopodia and other projections from the cell. Gels composed of short, randomly orientated filaments are found in the cortical region of the cell.

### Small GTPases

There are three well-known GTPases, which activate cell movement in response to extracellular signals: Rho, Rac, and cdc42. They are activated by numerous tyrosine kinase-, G-coupled-, and cytokine-type receptors. Activation involves exchange of GDP for GTP, and many downstream proteins can interact with the activated forms. Rho normally activates the assembly of stress fibers. Rac activates the formation of lamellipodia and ruffles. Cdc42 activates formation of filopodia. In addition, all three promote the formation of focal adhesions, which are integrin-containing junctions to the extracellular matrix. These proteins can also affect gene activity through the kinase cascade signal transduction pathways.

## VI. CELL ADHESION MOLECULES

Organisms are not just bags of cells; rather, each tissue has a definite cellular composition and microarchitecture. This is determined partly by the cell surface molecules, by which cells interact with each other, and partly by the components of the extracellular matrix (ECM). Virtually all proteins on the cell surface or in the ECM are glycoproteins,

**FIG. 5.8.** Cell adhesion molecules. (a) Calcium-dependent system. (b) Calcium-independent system. (c) Adhesion to the extracellular matrix. (From Slack, 2005.)

containing oligosaccharide groups added in the endoplasmic reticulum or Golgi apparatus after translation and before secretion from the cell. These carbohydrate groups often have rather little effect on the biological activity of the protein, but they may affect its physical properties and stability.

Cells are attached to each other by *adhesion molecules* (Fig. 5.8). Among these are the *cadherins*, which stick cells together in the presence of Ca, the *cell adhesion molecules* (CAMs), which do not require Ca, and the *integrins*, which attach cells to the extracellular matrix. When cells come together they often form *gap junctions* at the region of contact. These consist of small pores joining the cytosol of the two cells. The pores, or *connexons*, are assembled from proteins called *connexins*. They can pass molecules up to about 1000 molecular weight by passive diffusion.

Cadherins are a family of single-pass transmembrane glycoproteins that can adhere tightly to similar molecules on other cells in the presence of calcium. They are the main

factors attaching embryonic cells together, which is why embryonic tissues can often be caused to disaggregate simply by removal of calcium. The cytoplasmic tail of cadherins is anchored to actin bundles in the cytoskeleton by a complex including proteins called *catenins*. One of these,  $\beta$ -catenin, is also a component of the important Wnt signaling pathway, providing a link between cell signaling and cell association. Cadherins were first named for the tissues in which they were originally found, so E-cadherin occurs mainly in epithelia and N-cadherin occurs mainly in neural tissue.

The immunoglobulin superfamily is made from single-pass transmembrane glycoproteins, with a number of disulphide-bonded loops on the extracellular region, similar to the loops found in antibody molecules. They also bind to similar molecules on other cells; but, unlike the cadherins, they do not need calcium to do so. The neural cell adhesion molecule (N-CAM) is composed of a large family of different proteins formed by alternative splicing. It is most prevalent in the nervous system but also occurs elsewhere. It may carry a large amount of polysialic acid on the extracellular domain, and this can inhibit cell attachment because of the repulsion between the concentrations of negative charge on the two cells. Related molecules include L1 and ICAM (intercellular cell adhesion molecule).

The integrins are cell-surface glycoproteins that interact mainly with components of the extracellular matrix. They are heterodimers of  $\alpha$  and  $\beta$  subunits and require either magnesium or calcium for binding. There are numerous different  $\alpha$  and  $\beta$  chain types, and so there is a very large number of potential heterodimers. Integrins are attached by their cytoplasmic domains to microfilament bundles, so, like cadherins, they provide a link between the outside world and the cytoskeleton. They are also thought on occasion to be responsible for the activation of signal transduction pathways and new gene transcription following exposure to particular extracellular matrix components.

## VII. EXTRACELLULAR MATRIX

*Glycosaminoglycans* (GAGs) are unbranched polysaccharides composed of repeating disaccharides of an amino sugar and a uronic acid, usually substituted with some sulphate groups. GAGs are constituents of proteoglycans, which have a protein core to which the GAG chains are added in the Golgi apparatus before secretion. One molecule of a proteoglycan may carry more than one type of GAG chain. GAGs have a high negative charge, and a small amount can immobilize a large amount of water into a gel. Important GAGs, each of which has different component disaccharides, are heparan sulphate, chondroitin sulphate, and keratan sulphate. Heparan sulphate, closely related to the anticoagulant heparin, is particularly important for cell signaling, because it is required to present various growth factors, such as the fibroblast growth factors (FGFs), to their receptors. Hyaluronic acid differs from other GAGs because

it occurs free and not as a constituent of a proteoglycan. It consists of repeating disaccharides of glucuronic acid and *N*-acetyl glucosamine, and it is not sulphated. It is synthesized by enzymes at the cell surface and is abundant in early embryos.

*Collagens* are the most abundant proteins by weight in most animals. The polypeptides, called  $\alpha$  chains, are rich in proline and glycine. Before secretion, three  $\alpha$  chains become twisted around each other to form a stiff triple helical structure. In the extracellular matrix, the triple helices become aggregated together to form the collagen fibrils visible in the electron microscope. There are many types of collagen, which may be composed of similar or of different  $\alpha$  chains in the triple helix. Type I collagen is the most abundant and is a major constituent of most extracellular material. Type II collagen is found in cartilage and in the notochord of vertebrate embryos. Type IV collagen is a major constituent of the basal lamina underlying epithelial tissues. Collagen helices may become covalently cross-linked through their lysine residues, and this contributes to the changing mechanical properties of tissues with age.

*Elastin* is another extracellular protein with extensive intermolecular cross-linking. It confers the elasticity on tissues in which it is abundant, and it also has some cell signaling functions.

*Fibronectin* is composed of a large disulphide-bonded dimer. The polypeptides contain regions responsible for binding to collagen, to heparan sulphate, and to integrins on the cell surface. These latter, cell-binding domains are characterized by the presence of the amino acid sequence Arg-Gly-Asp (= RGD). There are many different forms of fibronectin produced by alternative splicing.

*Laminin* is a large extracellular glycoprotein, found particularly in basal laminae. It is composed of three disulphide-bonded polypeptides joined in a cross shape. It carries domains for binding to type IV collagen, heparan sulphate, and another matrix glycoprotein, entactin.

## VIII. CULTURE MEDIA

Mammalian cells will only remain in good condition very close to the normal body temperature, so good temperature control is essential. Because water can pass across the plasma membranes of animal cells, the medium must match the osmolarity of the cell interior, otherwise cells will swell or shrink due to osmotic pressure difference. Mammalian cell media generally have a total osmolarity about 350 mosm. The pH needs to be tightly controlled; usually 7.4 is normal. The pH control is typically achieved with bicarbonate-CO<sub>2</sub> buffers (2.2 gm/L bicarbonate and 5% CO<sub>2</sub> being a common combination). These give better results with most animal cells than other buffers, perhaps because bicarbonate is also a type of nutrient. The medium must contain a variety of components: salts, amino acids, and sugars plus low levels of specific hormones and growth factors required for the particular cells in question. Because

of the complexity of tissue culture media, they are rarely optimized for a given purpose by varying every one of the components. Usually changes are incremental and the result of a "gardening" approach rather than a systematic one.

The requirement for hormones and growth factors is usually met by including some animal serum, often 10% fetal calf serum. This is long-standing practice but has two substantial disadvantages. Serum can never be completely characterized, and there are often differences between batches of serum, which can be critical for experimental results. Also, there is currently a drive to remove serum from the preparation of cells intended for implantation into human patients. This is because of the perceived possibility, actually very remote, of transmitting animal diseases to patients. Assuming cells are kept in a near-optimal medium, they can, in principle, grow exponentially, with a constant doubling time. Indeed it is possible to grow many types of cells in exponential cultures, rather like microorganisms. In order to keep them growing at maximal rate, they need to have their medium renewed regularly and to be subcultured and replated at lower density whenever they approach confluence, which means covering all the available surface. Subculturing is usually carried out by treatment with the enzyme trypsin, which degrades much of the extracellular and cell surface protein and makes the cells drop off the substrate and become roughly spherical bodies in suspension. Once the trypsin is diluted out, the cells can be transferred at lower density into new flasks. The cells take an hour or two to resynthesize their surface molecules, and they can then adhere to the new substrate and carry on growing.

Although exponential growth is often sought and encountered in tissue culture, it is important to bear certain things in mind. First, cells very rarely grow exponentially in the body. Most cells are quiescent, rarely undergoing any division at all, thus resembling static confluent tissue cultures more than growing ones. Some tissues undergo continual renewal, such that the production of new cells is balanced by the death and shedding of old ones, so the cell number remains constant even though proliferation is occurring. Growth also involves increase of cell size, which depends largely on the overall rate of protein synthesis relative to protein degradation. This needs to balance cell division such that the volume should exactly double in each cell cycle. If it did not, then the cells would get progressively bigger or smaller.

### Cell Types

On the basis of light microscopy it is estimated that there are about 210 different types of differentiated cells in the mammalian body. This number is certainly an underestimate, since many subdivisions of cells cannot be seen in the light microscope, particularly the different types of neuron in the nervous system and different types of T-lymphocyte in the immune system. Cells types are differ-

**FIG. 5.9.** Most tissues are composed of epithelial (a) and mesenchymal (b) components. (From Slack, 2005.)

ent from one another because they are expressing different subsets of genes and hence contain different proteins. The products of a relatively small number of genes may dominate the appearance of a differentiated cell, for example, the proteins of the contractile apparatus of skeletal muscle are very abundant. However, a typical cell will express many thousands of genes, and its character will also depend on the genes that are not expressed. It is possible to control cell differentiation to some extent. Certain special culture media are favorable for differentiation of particular cell types, such as adipocytes, muscle, or bone. Also, some regulatory genes are known that can force the differentiation of a particular cell type if they are overexpressed. For example, the MyoD gene, encoding a basic helix-loop-helix transcription factor, will force differentiation of muscle in a wide range of cultured cells. The runt domain factor Cbfa-1 plays a similar role for the differentiation of bone.

In some cases differentiated cells can continue to grow in pure culture. But in many cases differentiation causes slowing or cessation of cell division. Furthermore, sometimes differentiated cells are formed from stem cells that undergo unequal divisions, yielding one differentiated daughter and one stem cell. In such cases it will not be possible to obtain a pure culture of a single differentiated cell type.

## IX. CELLS IN TISSUES

For the purposes of tissue engineering it is useful to consider how tissues are structured in the normal body. There is very wide range of arrangements, but we can cite some general principles.

- All tissues contain more than one cell type.
- These are drawn from different embryological lineages.

- Even more cell types may be generated *in situ*.
- A vascular supply is essential for survival.

From a morphological point of view, most cells can be regarded as epithelial or mesenchymal (Fig. 5.9). These terms relate to cell shape and behavior rather than to embryonic origin. An *epithelium* is a sheet of cells, arranged on a basement membrane, each cell joined to its neighbors by specialized junctions and showing a distinct apical-basal polarity. *Mesenchyme* is a descriptive term for scattered stellate cells embedded in loose extracellular matrix. It fills up much of the embryo and later forms fibroblasts, adipose tissue, smooth muscle, and skeletal tissues. A tissue normally has both an epithelial and a mesenchymal component. Usually these depend on each other: Each secretes growth factors needed by the other for its survival and proliferation.

The epithelium is usually the functional part of the tissue; for example, the epithelial linings of the various segments of the gut have specific properties of protection, absorption, or secretion, while the underlying mesenchyme provides mechanical support, growth factors, and physiological response, in terms of muscular movements.

Vertebrate epithelial cells are bound together by tight junctions, adherens junctions, and desmosomes, the latter two types involving cadherins as major adhesion components. Mesenchymal cells may also adhere by means of cadherins, but usually more loosely. The adhesion of early embryo cells is usually dominated by the cadherins, and because of this most types of early embryo can be fully disaggregated into single cells by removal of calcium from the medium.

There is some qualitative specificity to cell adhesion. Cadherin-based adhesion is homophilic, and so cells carry-

ing E-cadherin will stick more strongly to each other than to cells bearing N-cadherin. The calcium-independent immunoglobulin superfamily-based adhesion systems, such as N-CAM (neural cell adhesion molecule), particularly important on developing neurons and glia, are different again, and they also promote adhesion of similar cells. This qualitative specificity of adhesion systems provides a mechanism for the assembly of different types of cell aggregates in close proximity and also prevents individual cells from wandering off into neighboring domains. If cells with different adhesion systems are mixed, they will sort out into separate zones, eventually forming a dumbbell-like configuration or even separating altogether.

With the exception of the kidney, all other tissues draw their epithelium and mesenchyme from different germ layers of the embryo. The implication of this for tissue engineering is that it will probably be necessary to assemble tissues from separate epithelial and mesenchymal cells, designed such that each population can support the other.

Furthermore, the epithelium itself normally contains more than one cell type. Many tissues can be regarded as being organized into structural-proliferative units, of which the intestinal crypt serves as a good example. The small intestinal epithelium contains four cell types, all thought to be produced continually from a population of stem cells located near the base of the intestinal crypts. The four types are the absorptive cells, the goblet cells secreting mucus, the Paneth cells at the base of the crypts involved in defense against infection, and the endocrine cells, which themselves are of many subtypes, secreting a variety of hormones controlling the physiology of the gut.

The intestine also provides an example of a renewal tissue, already referred to, which means that the epithelium is in a state of constant turnover, with cells being

produced from the stem cells, dividing a few times, differentiating, and then dying and being shed from the tips of the villi. If tissues like this are going to be created by tissue engineers, they need to be organized into proliferative and differentiated zones, and this spatial organization needs to be stable, despite the flux of cells through the system.

The final consideration is that cells need a continuous supply of nutrients and oxygen and continuous removal of waste products. *In vivo* this is achieved by means of the blood vascular system, which culminates in capillary beds of enormous density such that all cells are within a few cell diameters of the blood. For tissue engineering the lesson is clear: It is possible to grow large avascular structures only so long as they are two-dimensional. For example, large sheets of epidermis a few cells thick can be grown *in vitro* and used successfully for skin grafting. But any tissue more than a fraction of a millimeter in thickness will need to be provided with some sort of vascular system.

Tissue engineering needs not attempt to copy everything found in the normal body. However, it is necessary to be aware of the constraints provided by the molecular biology of the cell. Factors to be considered include:

- How to keep cells in the desired state by providing the correct substrate and medium
- How to create an engineered tissue containing two or more cell types of different origins that can sustain one another
- How to provide a vascular system capable of delivering nutrients and removing waste products
- How to establish the structural-proliferative units of the tissue
- How to control cell division (renewal type with stem cells or quiescent type with regenerative growth)

### I. INTRODUCTION

Multicellular tissues exist in one of two types of cellular arrangements, epithelial or mesenchymal. Epithelial cells adhere tightly to each other at their lateral surfaces and to an organized extracellular matrix (ECM) at their basal domain, thereby producing a sheet of cells with an apical, or adhesion-free, surface. Mesenchymal cells, in contrast, are individual cells with a bipolar morphology that are held together as a tissue within a three-dimensional ECM. The conversion of epithelial cells into mesenchymal cells, an *epithelial-to-mesenchymal transition* (EMT), plays an essential role in embryonic morphogenesis as well as a number of disease states. The reverse process, whereby mesenchymal cells coalesce into an epithelium, is a *mesenchymal-to-epithelial transition* (MET). Understanding the molecular mechanisms of EMTs and METs offers important insights into the basic mechanistic processes of embryonic morphogenesis and tissue organization in the adult.

The early embryo is structured as one or more epithelia. The emergence of the EMT during evolution has allowed rearrangements of cells and tissues to create novel morphological features (reviewed in Hay, 2005). There are several well-studied examples of EMTs during embryonic development. The migration of sea urchin primary mesenchyme

cells (PMCs) from the vegetal plate of the blastocyst (epithelium) into the blastocoel cavity to initiate skeleton formation occurs by an EMT in the pregastrula embryo (reviewed in Shook and Keller, 2003). The process of gastrulation in amniotes (reptiles, birds, and mammals) occurs by an EMT as the epithelial epiblast at the primitive streak gives rise to mesenchymal cells—the precursors to mesoderm and endoderm. EMTs also occur later in vertebrate development, such as during the delamination of neural crest cells from the neural tube, the invasion of endothelial cells into the cardiac jelly to form the cardiac cushions, the formation of the sclerotome (connective tissue precursors) from epithelial somites, and the creation of mesenchymal cells in the palate from the epithelial seam where the palate shelves fuse (Hay, 2005; Shook and Keller, 2003). The reverse process of MET is likewise crucial to development, and examples include the condensation of mesenchymal cells to form the notochord and somites, kidney tubule formation from nephrogenic mesenchyme (Barasch, 2001), and the creation of heart valves from cardiac mesenchyme (Eisenberg and Markwald, 1995). In the adult organism, EMTs and METs occur during wound healing and tissue remodeling (Kalluri and Neilson, 2003). The conversion of neoplastic epithelial cells into invasive cancer cells is an EMT process (Thiery, 2002), as is the disintegration of epithelial kidney tissue into

fibroblastic cells during end-stage renal disease (Iwano *et al.*, 2002).

The focus of this chapter is on the molecular agents that control the organization of tissues into epithelium or mesenchyme. We first discuss the cellular changes that occur during the EMT, including changes in cell–cell and cell–ECM adhesions, changes in cell polarity, the stimulation of cell motility, and the increased protease activity that accompanies invasion of the basal lamina. Then we consider the molecules and mechanisms that control the EMT or MET, including the transcription factors that initiate the changes in gene activity involved in the EMT and the upstream signal transduction pathways that regulate these transcription factors. We also identify gaps in our current understanding of these regulatory processes.

## II. MOLECULAR MECHANISMS OF THE EMT

The conversion of an epithelial sheet into individual migratory cells requires the coordinated changes of many distinct families of molecules. As an example of a typical EMT, we give a brief overview of the ingression of PMCs that occurs in sea urchin embryos just prior to gastrulation (for a recent review see Shook and Keller, 2003). The pregastrula sea urchin embryo is a hollow sphere of epithelial cells (blastula) in which the basal domain of the epithelium rests on a basal lamina and faces the inner surface of the sphere. The apical domain, with its microvilli, comprises the outer surface of the sphere. As the primary mesenchyme cells detach from the epithelium to enter the blastocoel, the apical adherens junctions that tether them in the epithelium are endocytosed, and the PMCs lose cell–cell adhesion, gain adhesion to the inner basal lamina, and migrate on the inner surface of the blastocoel cavity. The basal lamina is degraded at sites where PMCs enter the blastocoel. Similar events are observed in other EMTs. Thus, the basic steps of an EMT are: (1) the loss of cell–cell adhesion, (2) the gain of cell–ECM adhesion, (3) change in cell polarity and the stimulation of cell motility, and (4) invasion across the basal lamina. We now examine the components of an EMT in more detail.

### Changes in Cell–Cell Adhesion

Epithelial cells are held together by specialized cell–cell junctions, including adherens junctions, desmosomes, and tight junctions. These are localized in the lateral domain near the apical surface and establish the apical polarity of the epithelium. In order for an epithelial sheet to produce individual migrating cells, cell–cell adhesions must be disrupted. The transmembrane proteins of the adherens junctions and desmosomes that mediate cell–cell adhesions are members of the cadherin superfamily. During the ingression of PMCs in sea urchin embryos, cadherin protein is lost from the lateral membrane domain, and cadherins

are subsequently found in subcellular vesicles, suggesting that the cadherins are endocytosed (Miller and McClay, 1997). Cadherins are essential for establishing adherens junctions and desmosomes and in maintaining the epithelial phenotype. E-cadherin and N-cadherin (*E* for epithelial and *N* for neuronal) are classical cadherins that interact homotypically through their extracellular IgG domains with like cadherins on adjacent cells. Function-blocking antibody against E-cadherin causes the epithelial Madin–Darby canine kidney (MDCK) cell line to dissociate into individual migratory cells (reviewed in Thiery, 2002), and E-cadherin-mediated adhesion is necessary to maintain the epithelial integrity of embryonic epidermis (Levine *et al.*, 1994). Furthermore, E-cadherin is sufficient for promoting cell–cell adhesion and assembly of adherens junctions, since the overexpression of E-cadherin in fibroblasts results in the formation of cell–cell adhesions (Nagafuchi *et al.*, 1987). In epithelial cancers (carcinomas), E-cadherin acts as a tumor suppressor by inhibiting invasion and metastasis. Partial or complete loss of E-cadherin in carcinomas is associated with increased metastasis, and conversely, E-cadherin overexpression in cultured cancer cells reduces invasiveness *in vitro* and *in vivo* (Thiery, 2002). In a mouse model for  $\beta$ -cell pancreatic cancer, the loss of E-cadherin is the rate-limiting step for transformed epithelial cells to become invasive (Perl *et al.*, 1998). Although the loss of cadherin-mediated cell–cell adhesion is necessary for an EMT, the loss of cadherins is not always sufficient to generate a complete EMT *in vivo*. For example, the neural tube epithelium in mice expresses N-cadherin and not E-cadherin; and in the N-cadherin knockout mouse, the neural tube is ill formed (cell adhesion defect), but an EMT is not induced (Radice *et al.*, 1997). Hence, cadherins are essential for maintaining epithelial integrity, and the loss of cell–cell adhesion due to the reduction of cadherin function is an important step in an EMT.

Changes in cadherin expression, or *cadherin switching*, is characteristic of an EMT or an MET. For example, epithelia that express E-cadherin will down-regulate its expression at the time of the EMT and express a different cadherin, such as N-cadherin. When mesenchymal tissue becomes epithelial again (MET), N-cadherin is lost and E-cadherin is re-expressed. Cadherin switching occurs during the EMT that generates the neural crest. Just before neural crest cells detach from the neural tube, N-cadherin is down-regulated, and the mesenchymal cadherins, cadherin-11 and cadherin-7, are expressed. When neural crest cells cease migration and coalesce into ganglia, they express N-cadherin again (Pla *et al.*, 2001). Likewise, in various cultured mammary epithelial cell lines, TGF- $\beta$  exposure results in the loss of E-cadherin, increased expression of N-cadherin, the loss of adherens junctions, and the induction of cell motility. N-cadherin misexpression in these cell lines is sufficient for increased cell motility in the absence of TGF- $\beta$ . Conversely, when N-cadherin expression is knocked

down by siRNA, the adherens junctions are still down-regulated in response to TGF- $\beta$ , but the cells do not become motile. Hence, while cadherin switching is not sufficient to bring about a complete EMT, cadherin switching is necessary for cell motility (Maeda *et al.*, 2005).

There are several ways that cadherin expression and function can be regulated. The transcription factors that are central to an EMT, such as Snail-1, Snail-2 (previously Snail and Slug, respectively, see Barrallo-Gimeno and Nieto, 2005, for nomenclature), Sip1,  $\delta$ EF-1, Twist, and E2A, all bind to the *E-cadherin* promoter and repress the transcription of E-cadherin (reviewed in De Craene *et al.*, 2005). At the protein level, E-cadherin is regulated by trafficking and protein turnover pathways. The precise endocytic pathways for E-cadherin are still unclear, and there is evidence for both caveolae-dependent endocytosis and clathrin-dependent endocytosis of E-cadherin (for a recent review, see Bryant and Stow, 2004). E-cadherin can also be ubiquitinated in cultured cells by the E3-ligase Hakai, which targets E-cadherin to the proteasome (Y. Fujita *et al.*, 2002). Another mechanism by which E-cadherin function is disrupted is through extracellular proteases, such as matrix metalloproteases, which degrade the extracellular domain of E-cadherin and consequently reduce cadherin-mediated cell–cell adhesion (Egeblad and Werb, 2002). Some or all of these mechanisms may occur simultaneously during an EMT to disrupt cell–cell adhesion and promote motility.

In some cases, the delamination of cells from an epithelium occurs without the complete loss of cell–cell adhesion. In the sea urchin species *Mespilia*, the loss of cell–cell adhesions by ingressing PMCs is incomplete, and the PMCs tear themselves away from the epithelium, leaving behind a portion of their apical domain. However, this inefficient loss of cell–cell adhesion is not observed in other sea urchin species, such as *Arbacia* and *Lytechinus* (Shook and Keller, 2003). Similarly, in the delamination of the cranial neural crest and neuronal precursors from the trigeminal placodes in mice, apical adhesions are not completely down-regulated, but rather, the adherens junctions of departing mesenchymal cells remain intact and are pulled along the plane of the membranes of adjacent epithelial cells until they eventually rupture (Nichols, 1987). Therefore, the importance of a complete loss of cell–cell adhesion in EMTs is debatable.

Another potential mechanism of delamination from an epithelial sheet involves an asymmetric cell division, in which the basal parent cell retains adherens junctions (and therefore remains tethered to the epithelium) while the apical daughter cell is separated from the adherens junctions by the cleavage furrow and is released from the epithelium. An asymmetric mitosis has not yet been associated with well-studied EMTs, but it has been observed in the detachment of neurons from the ventricular zone of the ferret brain (Chenn and McConnell, 1995), neuroblast delamination in *Drosophila* (Urbach *et al.*, 2003), and the

translocation of cells from the dermamyotome to the myotome (Gros *et al.*, 2005). These latter three events are not widely considered to be EMTs because the resultant cells do not exhibit complete mesenchymal behavior, such as active migration and invasiveness. At present, there is no direct evidence that an asymmetric cell division is involved in canonical EMTs, such as sea urchin PMC ingression, amniote primitive streak mesenchyme formation, neural crest delamination, and heart valve formation.

In summary, epithelial integrity is maintained principally by cadherins, and changes in cadherin expression are usually necessary for an EMT.

### Changes in Cell–ECM Adhesion

Altering the way that a cell interacts with the ECM is also important in EMTs and METs. For example, sea urchin PMCs lose cell–cell adhesions but simultaneously acquire adhesion to basal lamina components such as fibronectin and laminin during the EMT (Fink and McClay, 1985). Cell–ECM adhesion is mediated principally by integrins. Integrins are transmembrane proteins composed of two noncovalently linked subunits,  $\alpha$  and  $\beta$ , and require  $\text{Ca}^{2+}$  or  $\text{Mg}^{2+}$  for binding to ECM components, such as fibronectin, laminin, and collagen. The cytoplasmic domain of integrins links to the cytoskeleton and interacts with signaling molecules. Changes in integrin function are required for many EMTs. During neural crest delamination,  $\beta$ 1 integrin is necessary for neural crest adhesion to fibronectin, and it becomes functional just a few hours before the EMT occurs (Delannet and Duband, 1992). Likewise, as epiblast cells undergo an EMT to form mesoderm during mouse primitive streak formation, the cells exhibit increased adhesion to ECM molecules (for a review, see Hay, 2005). In both neural crest and primitive streak epiblast cells, inhibiting integrin function with function-blocking antibodies prevents cell migration. Various integrins are also markers for metastasis in certain cancers (reviewed in Hood and Cheresch, 2002). However, the misexpression of integrin subunits does not appear to be sufficient to bring about a full EMT *in vitro* (Valles *et al.*, 1996) or *in vivo* (Carroll *et al.*, 1998).

The presence and function of integrins can also be modulated in several ways. For example, the transcriptional activation of integrin  $\beta$ 6 during colon carcinoma metastasis is mediated by the transcription factor Ets-1 (Bates *et al.*, 2005). Membrane trafficking and ubiquitination may also regulate the presence of integrin protein at the cell surface, but at present this process is poorly characterized. More importantly, most integrins can cycle between “On” (high-affinity) and “Off” (low-affinity) states. This inside-out regulation of integrin adhesion occurs at the integrin cytoplasmic tail (Hood and Cheresch, 2002). In addition to integrin activation, the spatial arrangement of integrins on the cell surface — or clustering — also affects the overall strength of integrin–ECM interactions. The increased adhesiveness of integrins due to clustering (known as *avidity*)

can be activated by chemokines and is dependent on RhoA and phosphatidylinositol 3' kinase (PI3K) activity.

In summary, adhesion to the ECM is required for the EMT. Cell-ECM adhesions are maintained by integrins, and integrins have varying degrees of adhesiveness, depending on the presence, activity, or avidity of the integrin subunits.

### Changes in Cell Polarity and Stimulation of Cell Motility

In order for mesenchymal cells to migrate away after detaching from the epithelium, they also must become motile. The asymmetric arrangement of the cytoskeleton and organelles in epithelial versus mesenchymal cells produces a distinct cellular polarity. Epithelial cell polarity is characterized by cell-cell junctions found at the apical-lateral domain and integrin-mediated adhesions at the basal side contacting basal lamina. Mesenchymal cells in contrast do not have apical/basal polarity, but, rather, front-end/back-end polarity, with actin-rich lamellipodia and Golgi localized at the leading edge (reviewed in Hay, 2005). Molecules that establish cell polarity include Cdc42, PAK1, PI3K, PTEN, Rac, and the PAR proteins. For example, the loss of cell polarity in the TGF- $\beta$ -stimulated EMT of mammary epithelial cells in culture is mediated by the polarity protein Par6. The stimulated TGF- $\beta$  receptor II causes Par6 to activate the E3 ubiquitin ligase Smurf1, and Smurf1 then targets GTPase RhoA to the proteasome. The loss of RhoA activity results in the loss of cell-cell adhesion and epithelial cell polarity (Ozdamar *et al.*, 2005).

The cellular programs responsible for down-regulating cell-cell adhesion and stimulating cell motility are separable. For example, in Eph4 cells that undergo an EMT by activating the transcription factor Jun, there is a complete loss of epithelial polarity, but cell migration is not stimulated (Fialka *et al.*, 1996). Similarly there are two steps during the EMT that generates the cardiac cushion cells. First, the cardiac endothelium is activated, whereby the cells lose their adhesions to each other, become hypertrophic and polarize the Golgi toward one end of the cell. Second, these activated cells become motile and invasive (Boyer *et al.*, 1999). The process of mesenchymal motility begins with the polarization and elongation of the cell, followed by the extension of a lamellipodium in the direction of migration. The cell body is propelled forward by the contraction of actin-myosin cytoskeleton and traction provided by adhesion to the ECM. How cell motility is activated and the extent to which cell motility is required for an EMT must be the subject of further research.

### Invasion of the Basal Lamina

In most EMTs the emerging mesenchymal cells must penetrate a basal lamina. The basal lamina consists of ECM components such as collagen type IV, fibronectin, and laminin, and it functions to stabilize the epithelium and act

as a barrier to migratory cells (Erickson, 1987). One mechanism that cells use to breach the basal lamina is to produce enzymes that degrade it, including plasminogen activator and matrix-metalloproteases (MMPs). Plasminogen activator is associated with a number of EMTs, including neural crest delamination (Erickson and Isseroff, 1989) and the formation of cardiac cushion cells during heart morphogenesis (McGuire and Alexander, 1993). Experimentally blocking plasminogen activity reduces the number of migratory cells in either model system. MMPs are also involved in a number of EMTs. MMP-2 is necessary for the EMT that generates neural crest cells, because when inhibitors of MMP-2 are added to chicken embryos *in vivo* or if MMP-2 translation is blocked with MMP-2 antisense oligonucleotides, neural crest delamination — but not neural crest motility — is inhibited (Duong and Erickson, 2004). In mouse mammary cells, MMP-3 misexpression is sufficient for an EMT *in vitro* and *in vivo* (Sternlicht *et al.*, 1999). Recently, the mechanism for MMP-3-induced EMT was elucidated. MMP-3 misexpression induces an alternatively spliced form of Rac1 (Rac1b), which then causes an increase in reactive oxygen species (ROS) intracellularly. Either Rac1b activity or ROS are necessary and sufficient for an MMP-3-induced EMT. Rac1b or ROS can also induce the expression of the transcription factor Snail-1 (Radisky *et al.*, 2005). The role of Rac1b or ROS in an EMT is unexpected, and it is not known if they control other EMT events during development or pathogenesis.

## III. THE EMT TRANSCRIPTIONAL PROGRAM

At the foundation of every EMT or MET program are the transcription factors that control the expression of genes required for this cellular transition. While many of the transcription factors that regulate EMTs have been identified, the complex transcriptional networks are still incomplete. Here we review the transcription factors that are known to promote the various phases of an EMT: loss of cell-cell adhesion, increase in cell-ECM adhesion, stimulation of cell motility, and invasion across the basal lamina. Then we examine how these EMT transcription factors themselves are regulated at the transcriptional and protein levels.

### Transcription Factors That Regulate EMTs

The Snail family of zinc-finger transcription factors, including Snail-1 and Snail-2 (formerly Snail and Slug, see Barrallo-Gimeno and Nieto, 2005), are emerging as direct regulators of cell-cell adhesion and motility during EMTs (Barrallo-Gimeno and Nieto, 2005; De Craene and Nieto, 2005). Snail-1 and Snail-2 are evolutionarily conserved in vertebrates and invertebrates, and, to our knowledge, Snail-1 or Snail-2 is expressed singly or in combination during every EMT yet examined. Blocking Snail-2 in the chicken primitive streak or during neural crest delamination with

antisense oligos against *Snail-2* inhibits these EMTs (Nieto *et al.*, 1994). The disruption of *Snail-1* in mice is lethal early in gestation, and mutant embryos display defects in the primitive streak EMT required to generate mesoderm. While some mesodermal markers are expressed, these presumptive mesodermal cells still retain apical/basal polarity and adherens junctions, and express E-cadherin mRNA (Carver *et al.*, 2001). Snail-1 expression is sufficient for breast cancer recurrence in a mouse model *in vivo*, and high levels of Snail-1 expression predict the relapse of breast cancer in women (Moody *et al.*, 2005). One mode of Snail-1 or Snail-2 activity is to decrease cell–cell adhesion, particularly by repressing the *E-cadherin* promoter (reviewed in De Craene *et al.*, 2005). This repression requires the mSin3A corepressor complex and histone deacetylases. Snail-1 is also a transcriptional repressor of the tight junction proteins Claudin and Occludin (De Craene *et al.*, 2005). The misexpression of Snail-1 and Snail-2 leads to the transcription of genes important for cell motility. In MDCK cells, the misexpression of Snail-1 indirectly up-regulates fibronectin and vimentin, which are essential for mesenchymal cell adhesion (Cano *et al.*, 2000), and Snail-2 misexpression induces RhoB mRNA in avian neural crest cells (Del Barrio and Nieto, 2002). Snail-1 expression can also promote invasion across the basal lamina. In MDCK cells, the misexpression of Snail-1 indirectly up-regulates *mmp-9* transcription and subsequently increases basal lamina invasion (Jorda *et al.*, 2005). Hence, Snail-1 or Snail-2 is necessary and sufficient for bringing about many of the processes of an EMT, including loss of cell–cell adhesion, changes in cell polarity, gain of cell motility, and invasion of the basal lamina.

Snail-1 and Snail-2 have been well characterized as transcriptional *repressors*, and it is still mysterious how the expression of Snail-1 and Snail-2 results in the *activation* of genes important for an EMT. In the avian neural crest it was recently shown that the *Snail-2* promoter is activated by the binding of Snail-2 to an E-box motif, indicating that in this case Snail-2 can act as a transcriptional activator of itself (Sakai *et al.*, 2006). Hence, the role of Snail-2 (and also likely Snail-1) as a transcriptional repressor or activator may be context dependent. Much is still to be learned about the downstream roles of Snail-1 and Snail-2 in regulating genes critical to an EMT.

Two other zinc-finger transcription factors that regulate EMTs are delta-crystallin enhancer-binding factor 1 ( $\delta$ EF1; also known as ZEB1) and Smad-interacting protein-1 (Sip1, also known as ZEB2).  $\delta$ EF1 is necessary and sufficient for an EMT in mammary cells transformed by the transcription factor c-Fos in a process that is apparently independent of Snail-1 (Eger *et al.*, 2005). Sip1 is structurally similar to  $\delta$ EF1, and Sip1 overexpression is sufficient to down-regulate E-cadherin, dissociate adherens junctions, and increase motility in MDCK cells (Comijn *et al.*, 2001). The cranial neural crest cells of *Sip1* mutant mice do not undergo delamination properly (Wakamatsu *et al.*, 2001). Both  $\delta$ EF1 and Sip1 can

bind to the *E-cadherin* promoter and repress transcription (De Craene *et al.*, 2005).

The lymphoid enhancer-binding factor/T-cell factor (LEF/TCF) transcription factors also play a role in EMTs. For example, the misexpression of Lef-1 in cultured colon cancer cells causes the down-regulation of E-cadherin and loss of cell–cell adhesion. Reversing Lef-1 misexpression (by removing Lef-1 retrovirus from the culture medium) causes cultured cells to revert back to an epithelium (Kim *et al.*, 2002). One important role for the LEF/TCF transcription factors in EMTs is to activate genes that regulate cell motility. The LEF/TCF pathway activates the promoter of the L1 adhesion molecule, a protein that is associated with increased motility and invasive behavior of colon cancer cells (Gavert *et al.*, 2005).  $\beta$ -catenin and LEF/TCF activate the *fibronectin* gene (Gradl *et al.*, 1999), and LEF/TCF transcription factors also activate genes that are required for basal lamina invasion, including *mmp-3* and *mmp-7* (Gustavson *et al.*, 2004).

### Regulation of the Snail and LEF/TCF Transcription Factors

Given the importance of the Snail and LEF/TCF transcription factors in orchestrating the various phases of an EMT, we need to understand how these EMT-inducing transcription factors are themselves regulated. Transcription factor activity can be controlled both at the transcriptional and at the protein level.

The activation of *Snail-1* transcription in *Drosophila* requires the transcription factors Dorsal (NF- $\kappa$ B) and Twist, and the *Snail-1* promoter includes both Dorsal and Twist binding sites (reviewed in De Craene *et al.*, 2005). The human *Snail-1* promoter also has functional NF- $\kappa$ B sites; and in cultured human cells transformed by Ras and induced by TGF- $\beta$ , NF- $\kappa$ B is essential for EMT initiation and maintenance (Huber *et al.*, 2004). Also, a region of the *Snail-1* promoter is responsive to integrin-linked kinase (ILK) overexpression in cultured cells (reviewed in De Craene *et al.*, 2005), and preliminary results suggest that ILK can activate Snail-1 expression via poly-ADP-ribose polymerase (PARP, Lee *et al.*, 2006). There are also *Snail-1* transcriptional repressors. In breast cancer cell lines, metastasis-associated protein 3 (MTA3) binds directly to and represses the transcription of *Snail-1* in combination with the Mi-2/NuRD complex (N. Fujita *et al.*, 2003). MTA3 is induced by the estrogen receptor (ER, nuclear hormone) pathway, and the absence of ER signaling or MTA3 leads to the activation of *Snail-1* expression. This suggests a mechanism whereby loss of the estrogen receptor in breast cancer contributes to metastasis. The role of MTA3 in regulating the transcription of Snail-1 mRNA in other EMTs is not known.

*Snail-2* transcriptional regulators have also been identified. In *Xenopus*, the *Snail-2* promoter has functional LEF/TCF binding sites, and in the mouse, MyoD (transcription factor central to muscle cell development) binds to the

*Snail-2* promoter and activates *Snail-2* transcription. In humans, the oncogene E2A-HLF and the pigment cell regulator MITF also can bind to the *Snail-2* promoter and activate its transcription (De Craene *et al.*, 2005). As mentioned earlier, in the avian neural crest, *Snail-2* is also able to activate its own promoter, either alone or in synergy with Sox9 (Sakai *et al.*, 2006).

LEF/TCF transcription factors can be activated by TGF- $\beta$  signaling. For instance, exposure of the medial edge epithelium of the palatal shelves to TGF- $\beta$ 3 induces the binding of the phosphorylated Smads2/4 complex to the *Lef-1* promoter and activates *Lef-1* transcription (Nawshad and Hay, 2003). While  $\beta$ -catenin is necessary for the function of the LEF/TCF proteins, the presence of high levels of nuclear  $\beta$ -catenin is not necessary for the transcription of *Lef-1* in the fusion of the mouse palate (Nawshad and Hay, 2003). The misexpression of *Snail-1* also activates the transcription of  $\delta$ EF-1 and *Lef-1* through a yet unknown mechanism (see De Craene *et al.*, 2005).

The activity of EMT transcription factors is also regulated at the protein level, including protein stability (targeting to the proteasome) and nuclear localization. GSK-3 $\beta$ , the same protein kinase that phosphorylates  $\beta$ -catenin and targets it for destruction, also phosphorylates *Snail-1*. The human *Snail-1* protein contains two GSK-3 $\beta$  phosphorylation consensus sites between amino acids 97–123. Inhibiting GSK-3 $\beta$  prevents *Snail-1* degradation and results in the loss of E-cadherin in cultured epithelial cells (Zhou *et al.*, 2004). Therefore, the inhibition of GSK-3 $\beta$  activity by Wnt signaling may have multiple roles in an EMT, leading to the stabilization of both  $\beta$ -catenin and *Snail-1*. Two other proteins that play a role in preventing GSK-3 $\beta$ -mediated phosphorylation of *Snail-1* are lysyl-oxidase-like proteins LOXL2 and LOXL3. LOXL2 and LOXL3 form a complex with the *Snail-1* protein near the GSK-3 $\beta$  phosphorylation sites, thus preventing GSK-3 $\beta$  from interacting with *Snail-1*. The misexpression of LOXL2 or LOXL3 reduces *Snail-1* protein degradation and induces an EMT in cultured epithelial cells (Peinado *et al.*, 2005). The importance of LOXL2 and LOXL3 in other EMTs is not yet known.

The function of *Snail-1* also depends on its nuclear localization. *Snail-1* has a nuclear localization sequence (NLS). The phosphorylation of human *Snail-1* by p21-activated kinase 1 (Pak1) at Ser<sup>246</sup> promotes the nuclear localization of *Snail-1* (and therefore *Snail-1* activation) in breast cancer cells. Pak1 can be activated by RTK signaling, and knocking down Pak1 by siRNA blocks Pak1-mediated *Snail-1* phosphorylation, increases the cytoplasmic accumulation of *Snail-1*, and reduces the invasive behavior of these breast cancer cells (Yang *et al.*, 2005). The protein that mediates the translocation of *Snail-1* into the nucleus in human cells is not yet known, although a *Snail-1* nuclear importer has been described in zebrafish. The zinc-finger transporting protein LIV1 is required for *Snail-1* to localize to the nucleus during zebrafish gastrulation, and LIV1 is activated by STAT3 signaling (Yamashita *et al.*, 2004). In

zebrafish, the protein kinase that phosphorylates the NLS sequence of *Snail-1* to promote the translocation of *Snail-1* to the nucleus has not yet been identified. *Snail-1* also contains a nuclear export sequence (NES) at amino acids 132–143 that is necessary and sufficient for the export of *Snail-1* from the nucleus to the cytoplasm and is dependent on the calreticulin nuclear export pathway (Dominguez *et al.*, 2003). This NES sequence is activated by the phosphorylation of the same lysine residues targeted by GSK-3 $\beta$ , which suggests a mechanism whereby phosphorylation of *Snail-1* by GSK-3 $\beta$  results in the export of *Snail-1* from the nucleus.

LEF/TCF transcriptional activity is also regulated by other proteins.  $\beta$ -catenin is required as a cofactor for the activation of LEF/TCF transcription factors, and *Lef-1* can also associate with cofactor Smads to activate the transcription of additional EMT genes (Labbe *et al.*, 2000).

In summary, EMT transcription factors such as *Snail-1* and *Lef-1* are regulated by a variety of mechanisms, both at the transcriptional level and at the protein level by protein degradation, nuclear localization, and cofactors. Many questions remain. What activates *Snail-1* transcription? What promoters are targeted by the *Snail* and LEF/TCF transcription factors? And what other cofactors regulate *Snail-1* and *Snail-2*?

## IV. MOLECULAR CONTROL OF THE EMT

The initiation of an EMT or an MET is a tightly regulated event during development and tissue repair, since the deregulation of either program is disastrous to the organism. A variety of external and internal signaling mechanisms coordinate the complex events of the EMT, and these same signaling pathways are often disrupted or reactivated during disease. Many of the molecules that trigger EMTs or METs have been identified, and in some cases the downstream effectors are known. EMTs or METs can be induced by either diffusible signaling molecules or ECM components, and these inductive signals act either directly on cell adhesion/structural molecules themselves or by regulating EMT transcriptional regulators. We first discuss the role of signaling molecules and ECM in triggering an EMT, and then we present a summary model for the induction of EMTs.

### Signaling Molecules

During development, five ligand–receptor signaling pathways are primarily employed: TGF- $\beta$ , Wnt, RTK, Notch, and Hedgehog signaling pathways. These pathways all have a role in triggering EMTs. Although the activation of a single signaling pathway can be sufficient for an EMT, in most cases an EMT or MET is initiated by multiple signaling pathways acting in concert.

#### TGF- $\beta$ Pathway

The transforming growth factor-beta (TGF- $\beta$ ) superfamily includes TGF- $\beta$ , activin, and bone morphogenetic protein (BMP) families. These ligands signal through recep-

tor serine/threonine kinases to activate a variety of signaling molecules, including Smads, MAPK, PI3K, and ILK. Most of the EMTs studied to date are induced, in part or solely, by TGF- $\beta$  superfamily members (for a recent review, see Zavadil and Bottinger, 2005). During embryonic heart formation, an EMT occurs as the endocardium produces mesenchymal cells that invade the cardiac jelly to form the endocardial cushions (reviewed in Eisenberg and Markwald, 1995). In chicken embryos, TGF- $\beta$ 2 and TGF- $\beta$ 3 have sequential and necessary roles in activating the endocardium and in signaling mesenchymal invasion, respectively (Camenisch *et al.*, 2002a). The TGF- $\beta$  superfamily member BMP2 may play a similar role in the mouse, since in *BMP2* or *BMP receptor 1A* (*BMPRIA*) mouse mutants the EMT that generates endocardial cushion cells does not occur. Moreover, BMP2 can induce this EMT *in vitro* (Sugi *et al.*, 2004). TGF- $\beta$ 3 also triggers the EMT that occurs in the fusing palate of mice (Nawshad *et al.*, 2004). In the avian neural crest, BMP4 induces *Snail-2* expression, an important transcription factor in the neural crest EMT (Liem *et al.*, 1995).

In the EMT that transforms epithelial tissue into metastatic cancer cells, it is generally accepted that TGF- $\beta$  can act both as a tumor suppressor and as a tumor/EMT inducer. For example, transgenic mice expressing TGF- $\beta$ 1 in keratinocytes are more resistant to the development of chemically induced skin tumors than controls, suggesting a tumor suppressor effect of TGF- $\beta$ 1 on epithelial cells. However, a greater portion of the tumors that do form in the keratinocyte-TGF- $\beta$ 1 transgenic mice are highly invasive spindle-cell carcinomas, indicating that TGF- $\beta$ 1 can induce an EMT in later stages of skin cancer development (Cui *et al.*, 1996). Similar effects of TGF- $\beta$  are observed in breast cancer progression, where the TGF- $\beta$  pathway initially inhibits tumor growth but later promotes metastasis to the lung (Zavadil and Bottinger, 2005). Expression of dominant-negative TGF- $\beta$ RII in cancer cells transplanted into nude mice blocks TGF- $\beta$ -induced metastasis (Portella *et al.*, 1998). Multiple signaling pathways may be involved in TGF- $\beta$ -induced EMT. For example, in cultured breast cancer cells, activated Ras and TGF- $\beta$  induce an irreversible EMT (Janda *et al.*, 2002); and in pig thyroid epithelial cells, TGF- $\beta$  and epidermal growth factor (EGF) synergistically stimulate the EMT (Grande *et al.*, 2002).

One outcome of TGF- $\beta$  signaling is to immediately signal changes in cell polarity. As cited earlier, in TGF- $\beta$ -induced EMTs of mammary epithelial cells, TGF- $\beta$ RII phosphorylates the polarity protein, Par6, and phosphorylated Par6 causes the E3 ubiquitin ligase, Smurf1, to target the GTPase, RhoA, for degradation. RhoA is required for the stability of tight junctions, and loss of RhoA leads to their dissolution (Ozdamar *et al.*, 2005). TGF- $\beta$  signaling also regulates gene expression through the phosphorylation and activation of several Smads. Smad3 is necessary for a TGF- $\beta$ -induced EMT, since the deletion of Smad3 in a mouse model leads to the inhibition of injury-induced lens and kidney tissue EMT (Roberts *et al.*, 2006). The precise role of

Smads in EMTs and the gene targets that Smads regulate will require further investigation. TGF- $\beta$ RI can also bind to and activate PI3K (Yi *et al.*, 2005), which in turn can activate ILK and downstream pathways.

ILK is emerging as an important positive regulator of EMTs (reviewed in Larue and Bellacosa, 2005). ILK has binding sites to allow interactions with integrins, the actin skeleton, focal adhesion complexes, PI3K, and growth factor receptors (TGF- $\beta$ , Wnt, or RTK). ILK can directly phosphorylate and regulate either Akt or GSK-3 $\beta$ , and ILK activity indirectly results in the activation of downstream transcription factors such as AP-1, NF- $\kappa$ B, and Lef1. Overexpression of ILK in cultured cells causes the suppression of GSK-3 $\beta$  activity (Delcommenne *et al.*, 1998), translocation of  $\beta$ -catenin to the nucleus, activation of Lef-1/ $\beta$ -catenin transcription factors, and the down-regulation of E-cadherin (Novak *et al.*, 1998). Inhibition of ILK in cultured colon cancer cells leads to the stabilization of GSK-3 $\beta$  activity and decreased nuclear  $\beta$ -catenin localization and results in the suppression of *Lef-1* and *Snail-1* transcription and the reduced invasive behavior of these colon cancer cells (Tan *et al.*, 2001). ILK activity also results in the expression of MMPs via Lef-1 transcriptional activity (Gustavson *et al.*, 2004). Hence, ILK (inducible by TGF- $\beta$  signaling) is capable of orchestrating major events in an EMT, including the loss of cell-cell adhesion and invasion across the basal lamina.

#### Wnt Pathway

Many EMTs or METs are also regulated by Wnt signaling. Wnts signal through seven-pass transmembrane proteins of the Frizzled family and activate G-proteins, PI3K, and  $\beta$ -catenin nuclear signaling. During zebrafish gastrulation, Wnt11 activates the GTPase Rab5c, which results in the endocytosis of E-cadherin and subsequent loss of cell-cell adhesion (Ulrich *et al.*, 2005). Wnt6 signaling is sufficient for the induction of *Snail-2* transcription in the neural crest in the chicken embryo, and perturbation of the Wnt pathway reduces neural crest induction (Garcia-Castro *et al.*, 2002). Wnts can also signal METs. For instance, Wnt4 is required for the coalescence of nephrogenic mesenchyme into epithelial tubules during murine kidney formation (Stark *et al.*, 1994), and Wnt6 is necessary and sufficient for the MET that forms somites (Schmidt *et al.*, 2004).

One of the downstream signaling molecules activated by Wnt signaling is  $\beta$ -catenin.  $\beta$ -catenin is a structural component of adherens junctions, acting as a bridge between cadherins and the cytoskeleton. Nuclear  $\beta$ -catenin is also a limiting factor for the activation of LEF/TCF transcription factors.  $\beta$ -catenin is pivotal for regulating most EMTs. In the sea urchin embryo,  $\beta$ -catenin expression is observed in the nuclei of PMCs prior to ingression, and nuclear  $\beta$ -catenin expression is lost in PMCs after the EMT is complete. Misexpression of an intracellular cadherin domain in sea urchin embryos to interfere with nuclear  $\beta$ -catenin signaling blocks the ingression of PMCs (Logan *et al.*, 1999). In mouse knockouts for  $\beta$ -catenin, the primitive streak EMT does not occur,

and no mesoderm is formed (Huelsken *et al.*, 2000).  $\beta$ -catenin is also necessary for the EMT that occurs during cardiac cushion development (Liebner *et al.*, 2004). In breast cancer,  $\beta$ -catenin expression is highly correlated with metastasis and poor survival (Cowin *et al.*, 2005), and blocking  $\beta$ -catenin function in tumor cells inhibits their invasion *in vitro* (Wong and Gumbiner, 2003). It is unclear if  $\beta$ -catenin overexpression alone is sufficient for all EMTs. If  $\beta$ -catenin is misexpressed in cultured cells, it causes apoptosis (Kim *et al.*, 2000). However, the misexpression of a stabilized form of  $\beta$ -catenin in mouse epithelial cells *in vivo* results in metastatic skin tumors (Gat *et al.*, 1998).

### Signaling by RTK Ligands

The receptor tyrosine kinase (RTK) family of receptors and the growth factors that activate them also regulate EMTs or METs. Ligand binding promotes RTK dimerization and activation of their intracellular kinase domains by the auto-phosphorylation of tyrosine residues. These phosphotyrosines act as docking sites for intracellular signaling molecules, which can activate signaling cascades such as Ras/MAPK, PI3K/Akt, JAK/STAT, and ILK. We now cite a few examples.

Hepatocyte growth factor (HGF, also known as scatter factor) acts through the RTK c-met. HGF is important for the MET in the developing kidney, since HGF/SF function-blocking antibodies inhibit the assembly of metanephric mesenchymal cells into kidney epithelium in organ culture (Woolf *et al.*, 1995). HGF signaling is required for the EMT that produces myoblasts (limb muscle precursors) from somite tissue in the mouse, because in knockout mice for c-met, myoblasts fail to detach from the myotome and migrate into the limb bud (reviewed in Thiery, 2002).

Fibroblast growth factor (FGF) signaling regulates mouse primitive streak formation. In FGFR1 mouse mutants, E-cadherin is not down-regulated,  $\beta$ -catenin does not relocate to the nucleus, *Snail-1* expression is down-regulated, and few FGFR1  $-/-$  cells contribute to the mesoderm. Interestingly, if E-cadherin function is also inhibited in FGFR1 mutants by the addition of function-blocking E-cadherin antibodies, the primitive streak EMT proceeds normally. The suggested mechanism is that failure to remove E-cadherin (mediated by FGFR1 signaling) allows E-cadherin to sequester cytoplasmic  $\beta$ -catenin and therefore attenuate later Wnt signaling required to complete the primitive streak EMT (Ciruna and Rossant, 2001). FGF signaling also stimulates cell motility and activates MMPs. In studies with various epithelial cultured cancer cells, sustained FGF2 and N-cadherin signaling results in increased cell motility (increased invasion of uncoated filters), MMP-9 activation, and the ability to invade ECM (invasion of matrigel-coated filters) (Suyama *et al.*, 2002).

Insulin growth factor (IGF) signaling can also induce an EMT. In epithelial cell lines derived from breast tumors, IGF receptor I (IGFR I) hyperstimulation results in increased cell

survival and motility, apparently through the activation of Akt2 and suppression of Akt1 (Irie *et al.*, 2005). In several cultured epithelial cell lines, IGFR1 is associated with the complex of E-cadherin and  $\beta$ -catenin, and the ligand IGF-II causes the redistribution of  $\beta$ -catenin from the membrane to the nucleus, activation of the transcription factor TCF-3, partial degradation of E-cadherin, and a subsequent EMT (Morali *et al.*, 2001).

Another RTK known for its role in EMTs is the ErbB2/HER-2/Neu receptor, whose ligand is heregulin/neuregulin. Overexpression of HER-2 occurs in 25% of human breast cancers, and the misexpression of HER-2 in mouse mammary tissue *in vivo* is sufficient to cause metastatic breast cancer (Muller *et al.*, 1988). Herceptin® (antibody against the HER-2 receptor) treatment is effective in reducing the recurrence of HER-2-positive metastatic breast cancers. HER-2 signaling activates *Snail-1* expression in breast cancer through an unknown mechanism (Moody *et al.*, 2005). Given these several examples, it appears that the RTK signaling pathway is important for the induction of EMTs.

### Notch Pathway

The Notch signaling family is well known for its role in cell specification, and it is now emerging as a regulator of EMTs. When the Notch receptor is activated by its ligand delta, an intracellular portion of the Notch receptor ligand is cleaved and transported to the nucleus, where it binds to the transcription factor Su(H) to regulate target genes. In zebrafish Notch1 mutants, cardiac endothelium expresses very little *Snail-1* and does not undergo the EMT required to make the cardiac cushions (Timmerman *et al.*, 2004). This mutation can be phenocopied by treating embryonic heart explants with inhibitors of the Notch pathway. Conversely, misexpression of activated Notch1 is sufficient to activate *Snail-1* expression and promote an EMT in cultured endothelial cells. In the heart, Notch functions via lateral induction to make cells competent to respond to TGF- $\beta$ 2, which we have previously discussed as a regulator of the cardiac cushion EMT (Timmerman *et al.*, 2004). In the avian neural crest EMT, Notch signaling is required for the induction and/or maintenance of *BMP4* expression and, hence, the EMT (Endo *et al.*, 2002). Similarly, Notch signaling is required for the TGF- $\beta$ -induced EMT of epithelial cell lines. The use of antisense oligonucleotides against Hey1 mRNA, siRNA against Jagged1 mRNA (encodes a Notch-ligand), or  $\gamma$ -secretase inhibitor GSI treatment (to block Notch receptor activation) each can inhibit a TGF- $\beta$ -induced EMT (Zavadil *et al.*, 2004). Therefore, the general role of Notch signaling in EMTs may be to induce competence to undergo an EMT in response to TGF- $\beta$  signaling.

### Hedgehog Pathway

The hedgehog pathway also regulates EMTs. Metastatic prostate cancer cells express high levels of hedgehog and *Snail-1*. If prostate cancer cell lines are treated with the

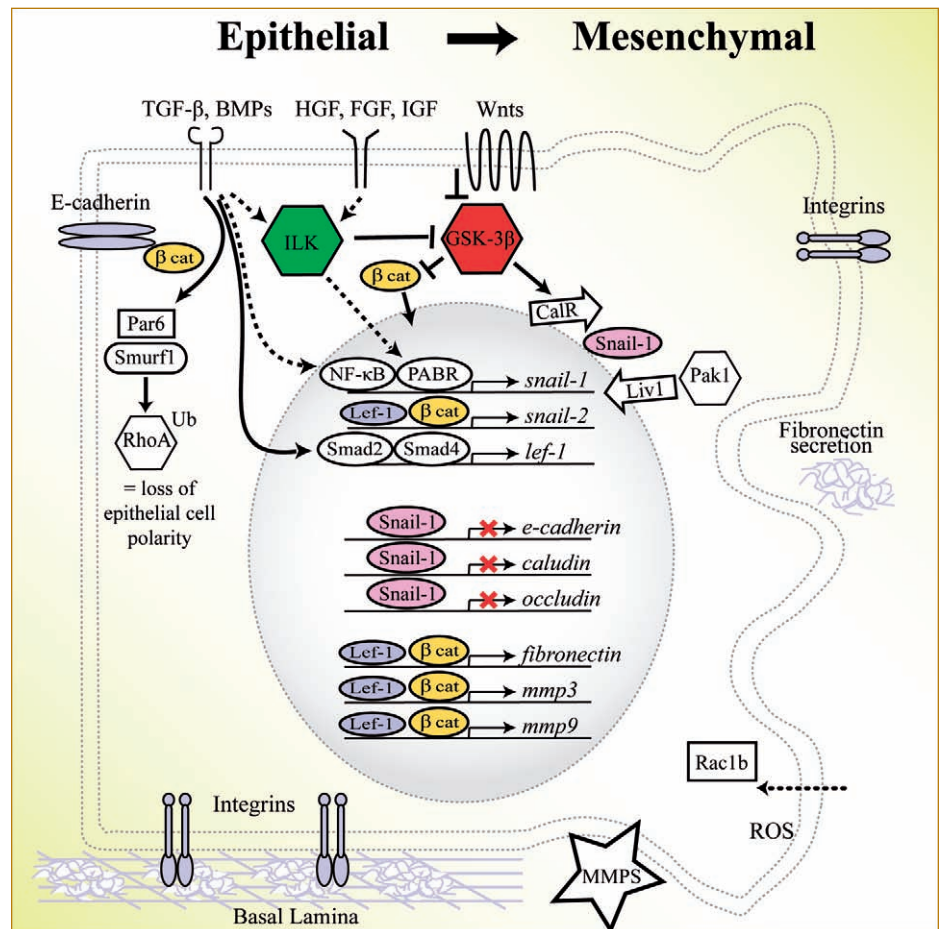

hedgehog-pathway inhibitor, cyclopamine, levels of *Snail-1* are decreased. Likewise, if the hedgehog-activated transcription factor, Gli, is misexpressed, *Snail-1* mRNA expression increases and E-cadherin mRNA levels decrease (Karhadkar *et al.*, 2004).

### ECM Signaling

In addition to diffusible signaling molecules, the extracellular environment can regulate EMTs or METs. This was first dramatically demonstrated when lens or thyroid epithelium was embedded in collagen gels, and they promptly underwent an EMT (reviewed in Hay, 2005). Integrin signaling appears to be important in this process, because if function-blocking antibodies against integrins are present in the collagen gels, the EMT is inhibited (Zuk and Hay, 1994). Hyaluronan is another ECM component that may regulate EMTs. In the hyaluronan synthase-2 knockout mouse (*Has2*<sup>-/-</sup>, which has defects in hyaluronan synthesis and secretion), the cardiac endothelium fails to undergo an EMT and produce the migratory mesenchymal cells to form the heart valve. The role of hyaluronan in this EMT may be to activate the RTK ErbB2/HER-2/Neu, because

treating cultured *Has2*<sup>-/-</sup> heart explants with heregulin (ligand for ErbB2) rescues the EMT. Consistent with this hypothesis, treating cardiac explants with hyaluronan activates ErbB2, and blocking ErbB2 signaling with the drug herstatin reproduces the *Has2*-knockout phenotype (Camenisch *et al.*, 2002b). A third ECM component that can stimulate an EMT is the gamma-2 chain of laminin 5, which is cleaved from laminin 5 by MMP-2. The gamma-2 chain causes the scattering and migration of epithelial cancer cells (Koshikawa *et al.*, 2000) and may be a marker of epithelial tumor cell invasion (Katayama *et al.*, 2003).

During EMT, the loss of cadherin expression is associated with the gain of integrin function. One molecule that has been shown to coordinate the loss of cell-cell adhesion with the gain of cell-ECM adhesion during EMT is the GTPase Rap1. In several cultured cell lines, the endocytosis of E-cadherin activates the Ras family member Rap1. Activated Rap1 is required to form integrin-mediated adhesions, since the overexpression of the Rap1-inactivating enzyme, Rap1GAPv, blocks integrin-ECM adhesion formation (Balzac *et al.*, 2005). The molecules with which Rap1 interacts to activate integrin function are not yet known.

**FIG. 6.1.** Induction of an EMT. This summary figure emphasizes some of the important molecules that bring about an EMT. The direct action of proteins on downstream targets are indicated by solid arrows, whereas a dashed arrow represents signaling pathways that are not yet defined. Progression of the EMT proceeds from left to right.

## A Framework for EMT Induction

Much of the experimental work on EMT mechanisms is piecemeal, and in no system is the entire inductive pathway and downstream effectors for an EMT completely worked out. However, developing a framework in an attempt to define the EMT molecular pathways can lead to insights and testable hypotheses. Figure 6.1 summarizes many of the various signaling mechanisms, although in reality only a few of the inductive signals and pathways may be utilized in particular EMT events. From experimental evidence to date, it appears that many of the EMT signaling pathways converge on ILK and nuclear  $\beta$ -catenin signaling to activate Snail and LEF/TCF transcription factors. Snail and LEF/TCF transcription factors then act on a variety of targets to suppress cell–cell adhesion, induce changes in cell polarity, stimulate cell motility, and promote invasion of the basal lamina (see Fig. 6.1).

## V. CONCLUSION

Over the past 20+ years since the term *EMT* was coined (reviewed in Thiery, 2002), important insights have been made in this rapidly expanding field of research. EMT and MET events occur during development and disease, and many of the molecules that regulate the various EMTs or METs have been characterized, thanks in large part to the advent of cell culture models. Despite this progress, there are still major gaps in our understanding of the regulatory networks for any EMT or MET. Mounting evidence suggests that disease processes such as the metastasis of epithelial-derived cancers and kidney fibrosis are regulated by the same molecular mechanisms that allow an epithelium to produce migratory and invasive cells during development. A clearer understanding of EMT and MET pathways in the future will lead to more effective strategies for tissue engineering and novel therapeutic targets.

### I. INTRODUCTION

Most of the success in performing tissue and organ replacement that has led to improvement in patient length/quality of life and health care can be attributed to the interdisciplinary approaches to tissue engineering. Today, scientists with diverse backgrounds, including molecular, cellular, and developmental biologists, collaborate with bioengineers to develop tissue analogues that allow physicians to improve, maintain, and restore tissue function. Several approaches have been taken to achieve these goals. One approach involves the use of matrices containing specific cells and growth factors. Recently, therapies based on stem cells are being implemented in conjunction with specific matrices and growth factors. Investigations of the basic cell and molecular mechanisms of the interactions between cells and extracellular matrix (ECM) during development and development-like processes such as wound healing, have contributed to advancements in preparation of tissue substitutes. In this article, we provide an historical perspective on the importance of ECM in cell and tissue function, discuss some of the key findings that led to the understanding of how the dynamics of cell–ECM interactions contribute to cell migration, proliferation, differentiation, and programmed death, all of which are important parameters to consider when preparing and using tissue analogues.

### Historical Background

In the first part of the last century, the extracellular matrix (ECM) was thought to serve only as a structural support for tissues. However, in 1966 Hauschka and Konigsberg showed that interstitial collagen promotes the conversion of myoblasts to myotubes, and shortly thereafter it was shown that both collagen and glycosaminoglycans are crucial for salivary gland morphogenesis. Based on these and other findings, in 1977 Hay put forth the idea that the ECM is an important component in embryonic inductions, a concept that implicated the presence of binding sites (receptors) for specific matrix molecules on the surface of cells. The stage was then set for further investigations into the mechanisms by which ECM molecules influence cell behavior. Bissell and colleagues (1982) proposed the model of *dynamic reciprocity*. In this model, ECM molecules interact with receptors on the surface of cells, which then transmit signals across the cell membrane to molecules in the cytoplasm. These signals initiate a cascade of events through the cytoskeleton into the nucleus, resulting in the expression of specific genes, whose products, in turn, affect the ECM in various ways. Through the years, it has become clear that cell–ECM interactions participate directly in promoting cell adhesion, migration, growth, differentiation, and apoptosis (a form of programmed cell death) as well as in modu-

lating the activities of cytokines and growth factors and in directly activating intracellular signaling.

### ECM Composition

The ECM is a molecular complex that consists of molecules such as collagens, other glycoproteins, hyaluronic acid, proteoglycans, glycosaminoglycans, and elastins that reside outside the cells, and that harbor proteins, including growth factors, cytokines, and matrix-degrading enzymes and their inhibitors. The distribution and organization of these molecules is not static but, rather, varies from tissue to tissue and during development from stage to stage, which has significant implications for tissue function. For example, mesenchymal cells are immersed in an interstitial matrix that confers specific biomechanical and functional properties to connective tissue (Suki *et al.*, 2005), whereas epithelial and endothelial cells contact a specialized matrix, the basement membrane, via their basal surfaces only, conferring mechanical strength and specific physiological properties on the epithelia. This diversity of composition, organization, and distribution of ECM results not only from differential gene expression of the various molecules in specific tissues, but also from the existence of differential splicing and posttranslational modifications of those molecules. For example, alternative splicing may change the binding potential of proteins to other matrix molecules or to their receptors (Ghert *et al.*, 2001; Mostafavi-Pour *et al.*, 2001), and variations in glycosylation can lead to changes in cell adhesion (Anderson *et al.*, 1994).

The local concentration and biological activity of growth factors and cytokines can be influenced by the ECM serving as a reservoir that binds these molecules and protects them from being degraded, by presenting them more efficiently to their receptors, or by affecting their synthesis (Nathan and Sporn, 1991; Sakakura *et al.*, 1999; Miralem *et al.*, 2001). Growth factor binding to ECM molecules may also exert an inhibitory effect (Kupprion *et al.*, 1998; Francki *et al.*, 2003), and, in some cases, only particular forms of these growth factors and cytokines bind to specific ECM molecules (Pollock and Richardson, 1992; Poltorak *et al.*, 1997; Martins-Green *et al.*, 1996). Importantly, binding of specific forms of these factors to specific ECM molecules can lead to their localization to particular regions within tissues and affect their biological activities.

ECM/growth factor interactions can also involve the ability of specific domains of ECM molecules (e.g., laminin-5, tenascin-C, and decorin) to bind and activate growth factor receptors (Tran *et al.*, 2004); the EGF-like repeats of laminin and tenascin-C bind and activate the EGFR (Swindle *et al.*, 2001; Schenk *et al.*, 2003). In the case of laminin, the EGF-like repeats interact with EGFR following their release by MMP-mediated proteolysis (Schenk *et al.*, 2003), whereas tenascin-C repeats are thought to bind EGFR in the context of the full-length protein (Swindle *et al.*, 2001). Decorin also binds and activates EGFR, although this binding occurs via

leucine-rich repeats rather than EGF-like repeats (Santra *et al.*, 2002). This ability of ECM molecules to serve as ligands for growth factor receptors may facilitate a stable signaling environment for the associated cells due to the inability of the ligand either to diffuse or to be internalized, thus serving as a long-term pro-migratory and/or pro-proliferative signal (Tran *et al.*, 2004).

### Receptors for ECM Molecules

Integrins, a family of heterodimeric transmembrane proteins composed of  $\alpha$  and  $\beta$  subunits, were the first ECM receptors to be identified. At least 18  $\alpha$  and 8  $\beta$  subunits have been identified so far; they pair with each other in a variety of combinations, giving rise to a large family that recognizes specific sequences on the ECM molecules (Fig. 7.1; Hynes, 2002). Some integrin receptors are very specific, whereas others bind several different epitopes, which may be on the same or different ECM molecules (Fig. 7.1), thus facilitating plasticity and redundancy in specific systems (Dedhar, 1999; Hynes, 2002). Although the  $\alpha$  and  $\beta$  subunits of integrins are unrelated, there is 40–50% homology within each subunit, with the highest divergence in the intracellular domain of the  $\alpha$  subunit. All but one of these subunits ( $\beta_4$ ) have large extracellular domains and very small intracellular domains. The extracellular domain of the  $\alpha$  subunits contains four regions that serve as binding sites for divalent cations, which appear to augment ligand binding and increase the strength of the ligand–integrin interactions (Pujades *et al.*, 1997; Leitinger *et al.*, 2000).

Transmembrane proteoglycans are another class of proteins that can also serve as receptors for ECM molecules (Jalkehen, 1991; Couchman and Woods, 1996). Several proteoglycan receptors that bind to ECM molecules have been isolated and characterized. Syndecan, for example, binds cells to ECM via chondroitin- and heparan-sulfate glycosaminoglycans, whose composition varies based on the type of tissue in which syndecan is expressed. These differential glycosaminoglycan modifications alter the binding capacity of particular ligands (Salmivirta and Jalkanen, 1995). Furthermore, syndecan also associates with the cytoskeleton, promoting intracellular signaling events and cytoskeletal reorganization through activation of Rho GTPases (Bass and Humphries, 2002; Yoneda and Couchman, 2003). Another receptor, CD44, also carries chondroitin sulfate and heparan sulfate chains on its extracellular domain and undergoes tissue-specific splicing and glycosylation to yield multiple isoforms (Brown *et al.*, 1991; Ehnis *et al.*, 1996). One of the extracellular domains of CD44 is structurally similar to the hyaluronan-binding domain of the cartilage link protein and aggrecan, which suggested that CD44 also serves as a hyaluronan receptor. Using a variety of techniques involving antibody binding and mutagenesis, it has been shown that this domain of CD44, as well as an additional domain outside this region, can interact directly with hyaluronan. These regions can also mediate CD44 binding to other

**FIG. 7.1.** Members of the integrin family of ECM receptors and their respective ligands. These heterodimeric receptors are composed of one  $\alpha$  and one  $\beta$  subunit and are capable of binding a variety of ligands, including Ig superfamily cell adhesion molecules, complement and clotting factors, and ECM molecules. Cell–cell adhesion is largely mediated through integrins containing  $\beta_2$  subunits, while cell–matrix adhesion is mediated primarily via integrins containing  $\beta_1$  and  $\beta_3$  subunits. In general, the  $\beta_1$  integrins interact with ligands found in the connective tissue matrix, including laminin, fibronectin, and collagen, whereas the  $\beta_3$  integrins interact with vascular ligands, including thrombospondin, vitronectin, fibrinogen, and von Willebrand factor. *Abbreviations:* CO, collagens; C3bi, complement component; FG, fibrinogen; FN, fibronectin; FX, Factor X; ICAM-1, intercellular adhesion molecule-1; ICAM-2, intercellular adhesion molecule-2; ICAM-3, intercellular adhesion molecule-3; LN, laminin; OSP, osteopontin; TN, tenascin; TSP, thrombospondin; VCAM-1, vascular cell adhesion molecule-1; VN, vitronectin; vWF, von Willebrand factor; ECADH, E-cadherin; LAP $\beta$ 1, latent activating protein  $\beta$ 1.

proteoglycans, although hyaluronic acid is its primary ligand (Marhaba and Zoller, 2004). CD44 can also interact with collagen, laminin, and fibronectin, although the exact binding sites of these molecules to CD44, as well as the functional significance of such interactions *in vivo*, are not well understood (Ehnis *et al.*, 1996; Ponta *et al.*, 2003; Marhaba and Zoller, 2004). RHAMM (receptor for hyaluronate-mediated motility) has been identified as an additional hyaluronic acid receptor (Hardwick *et al.*, 1992), which is responsible for hyaluronic-acid-mediated cell motility in a number of cell types and also appears to be important in trafficking of hematopoietic cells (Pilarski *et al.*, 1999; Savani *et al.*, 2001).

Other cell surface receptors for ECM have also been identified. A nonintegrin 67-kDa protein known as the *elastin-laminin receptor* (ELR) recognizes the YIGSR sequence of laminin and the VGVAPG sequence of elastin, neither of which recognizes integrins. The ELR colocalizes with cytoskeleton-associated and signaling proteins on laminin ligation, suggesting a role in laminin-mediated signaling (Massia *et al.*, 1993; Bushkin-Harav and Littauer, 1998), and has more recently been implicated in the signaling downstream of elastin and laminin during mechanotransduction (Spofford and Chilian, 2003). CD36, another

receptor for ECM, functions as a scavenger receptor for long-chain fatty acids and oxidized LDL, but also binds collagen I and IV, thrombospondin, and malaria-infected erythrocytes to endothelial cells and some types of epithelial cells. Each of these ligands has a separate binding site, but all are located in the same external loop of CD36, and the intracellular signals occurring after ligand binding lead to activation of a variety of signal transduction molecules (Febbraio *et al.*, 2001). For example, the antiangiogenic effects of thrombospondin are dependent on signaling downstream of CD36 (Jimenez *et al.*, 2000). Another alternative type of cell surface receptor, annexin II, is known to interact with alternative splice variants of tenascin-C, potentially mediating the cellular responses to these various forms of tenascin C (Chung and Erickson, 1994). In addition, ECM molecules have been shown to bind and activate tyrosine kinase receptors, including the EGFR via EGF-like domains (see earlier) as well as the discoidin domain receptors DDR1 and DDR2. DDR1 and DDR2 function as receptors for various collagens and mediate cell adhesion and signaling events (Vogel *et al.*, 1997). The DDR receptors have also been implicated in ECM remodeling because their overexpression decreases the expression of multiple matrix molecules and their receptors, including collagen, syndecan-1,

and integrin  $\alpha_3$ , while simultaneously increasing MMP activity (Ferri *et al.*, 2004).

We first discuss selected examples that illustrate the dynamics of cell-ECM interactions during development and wound healing as well as the potential mechanisms involved in the signal transduction pathways initiated by these interactions. Finally, we discuss the implications of cell-ECM interactions in tissue engineering.

## II. CELL-ECM INTERACTIONS

Multiple biological processes, including those relevant to development and wound healing, require interactions between cells and their environment as well as modulation of such interactions. During development, the cellular cross-talk with the surrounding extracellular matrix promotes the formation of patterns, the development of form (morphogenesis), and the acquisition and maintenance of differentiated phenotypes during embryogenesis. Similarly, during wound healing these interactions contribute to the processes of clot formation, inflammation, granulation tissue development, and remodeling. As outlined earlier, the current body of research in the fields of both embryogenesis and wound healing implicates multiple cellular behaviors, including cell adhesion/deadhesion, migration, proliferation, differentiation, and apoptosis, in these critical events.

### Development

#### Adhesion and Migration

Today, there is a vast body of experimental evidence that demonstrates the direct participation of ECM in cell adhesion and migration. Some of the most compelling experiments come from studies in gastrulation, migration of neural crest cells (NCC), angiogenesis, and epithelial organ formation. Cell interactions with fibronectin are important during gastrulation. Microinjection of antibodies to fibronectin into the blastocoel cavity of *Xenopus* embryos causes disruption of normal cell movements and leads to abnormal development (Boucaut *et al.*, 1984a). Furthermore, injection of RGD-containing peptides (which compete with integrins for ECM binding) during this same stage of development induces randomization of the bilateral asymmetry of the heart and gut (Yost, 1992). Similarly, administration of RGD-containing peptides and/or antibodies to the  $\beta_1$  subunit of the integrin receptor for fibronectin perturbs gastrulation in salamander embryos (Boucaut *et al.*, 1984b; Yost, 1992). These effects are not unique to fibronectin. They can also be introduced by manipulation of other molecules; competition of heparan sulfate proteoglycans with heparin for target molecule binding perturbs gastrulation and neurulation (Erickson and Reedy, 1998).

The NCC develop in the dorsal portion of the neural tube just after closure of the tube, migrate extensively

throughout the embryo in ECM-filled spaces, and give rise to a variety of phenotypes. The importance of cell-ECM interactions in the deadhesion process is supported by studies performed in the white mutant of Mexican axolotl embryos. The NCC that give rise to pigment cells fail to emigrate from the neural tube in these embryos. But when microcarriers containing subepidermal ECM from normal embryos are implanted into the appropriate area in these mutants, the NCC pigment cell precursors emigrate normally (Perris and Perissinotto, 2000). An RGD domain-carrying ECM molecule is known to promote the secretion of adhesion-degrading enzymes on integrin ligation, thereby facilitating emigration (Damsky and Werb, 1992). This may be due primarily to the RGD domain of fibronectin, for fibronectin appears between chick NCC just prior to their emigration from the neural tube (Martins-Green and Bissell, 1995). This fibronectin may consist predominantly or exclusively of the RGD domain-carrying segment that, when bound to its integrin receptor, promotes secretion of adhesion-degrading enzymes, thereby facilitating emigration (Damsky and Werb, 1992). Indeed, microinjection of antibodies to fibronectin (Poole and Thiery, 1986) or to the  $\beta_1$  subunit of the integrin receptor (Bronner-Fraser, 1985) into the crest pathways in chick embryos reduces the number of NCC that leave the tube and causes abnormal neural tube development. Other ECM molecules, such as laminin, also affect NCC adhesion and migration. For example, the YIGSR synthetic peptide known to inhibit laminin binding to cells inhibits NCC migration (Runyan *et al.*, 1986). NCC migration on laminin may also involve ligation of  $\alpha_1\beta_1$  integrin, because function-blocking antibodies of this integrin largely prevent such migration *in vitro* (Desban and Duband, 1997).

Endothelial cell interactions with ECM molecules and the type and conformation of the matrix are also crucial during angiogenesis (the development of blood vessels from preexisting vessels; Li *et al.*, 2003). Early indications of the role of ECM in angiogenesis were observed when human umbilical vein endothelial cells (HUVEC) were cultured on matrigel, a matrix synthesized by Engelbreth-Holm-Swarm (EHS) tumors. This specialized matrix has many of the properties of basement membrane. It consists of large amounts of laminin as well as collagen IV, entactin/nidogen, and proteoglycans. When HUVEC are cultured on matrigel for 12 hours, they migrate and form tubelike structures. In contrast, when these cells are cultured with collagen I, they form tubelike structures only after they are maintained *inside* the gels for one week, at which time the cells have secreted their own basement membrane molecules (Kubota *et al.*, 1988; Grant *et al.*, 1989). The observation that tube formation occurs more rapidly on matrigel than within collagen gels strongly suggested an important role for one or more of the matrix molecules present within the basement membrane in the development of the capillary-like endothelial tubes. Indeed, laminin, the predominant matrix

molecule of the basement membrane, was later shown to participate in endothelial tube formation and angiogenesis. *In vitro*, antibodies against laminin prevented the formation of endothelial tubes on matrigel, whereas treatment with synthetic peptides containing the YIGSR sequence derived from the B1 chain of laminin facilitates tube formation (Grant *et al.*, 1989). Another sequence, SIKVAV, found in the laminin A chain, promotes endothelial cell adhesion, elongation, and angiogenesis (Grant *et al.*, 1992). Interestingly, application of YIGSR-containing synthetic peptides prevent endothelial cell migration and angiogenesis (Sakamoto *et al.*, 1991). It is possible that the YIGSR peptides exert antiangiogenic properties due to competition for receptor binding with the intact laminin present *in vivo*. Indeed, if YIGSR peptides can successfully compete with laminin, it is possible that the displacement of YIGSR in the context of the whole molecule by the soluble YIGSR peptides will alter the presentation of the ligand to its receptor, resulting in changes in mechanical resistance that alter signaling events downstream of the receptor, ultimately resulting in different cellular responses. A similar hypothesis has been proposed for the interactions of integrins with soluble versus intact ligands (Stupack and Chersesh, 2002). Although the mechanisms generating different cellular outcomes are currently unknown, the mere fact that soluble and intact ECM receptor ligands may, at times, lead to alternative outcomes is likely of importance *in vivo* following matrix degradation. During angiogenesis, for example, endothelial cell migration and invasion into surrounding tissues is accompanied by the activation of matrix-degrading enzymes, which then cleave the matrix and release both matrix-bound growth factors as well as ECM fragments, providing additional angiogenic or antiangiogenic cues to influence the process further (Rundhaug, 2005). As such, matrix molecules that initially facilitate angiogenesis may be proteolytically cleaved at later angiogenic stages to create YIGSR peptides or some other antiangiogenic matrix fragment, preventing additional blood vessel formation and/or resulting in vessel maturation (Sakamoto *et al.*, 1991). Thus, the temporal and spatial production and cleavage of matrix molecules may have important consequences for tissue homeostasis.

### Proliferation

Some of the effects of cell-ECM interactions modulate cell proliferation. For example, a domain in the A chain of laminin that is rich in EGF-like repeats stimulates proliferation of a variety of different cell lines, and the entire molecule appears to promote proliferation of bone marrow-derived macrophages. These pro-proliferative effects are likely mediated, at least in part, by the activation of the EGFR by the EGF-like repeats (Schenk *et al.*, 2003). In contrast, there are also matrix molecules that inhibit cell proliferation. Heparin and heparin-like molecules are inhibitors of vascular smooth muscle cell (VSMC) proliferation. The conditioned medium of endothelial cells cultured

from bovine aortas inhibits the proliferation of VSMC, and this inhibition is obliterated by treatment of the medium with heparinase but not with chondroitinases or proteases. This suggests that heparan-type molecules have a direct antiproliferative effect on aortic VSMC. However, it is also possible that heparinase treatment may release pro-proliferative molecules that interact with heparin or heparan sulfate, thus allowing them to interact with their receptors and either promote proliferation or block any antiproliferative effects. One such mitogenic heparin-binding ECM molecule is thrombospondin, which is known to exert its mitogenic activities on VSMC via its amino terminal heparin-binding domain. Heparin has been shown to block thrombospondin binding to smooth muscle cells and also to block its mitogenic effects (Majack *et al.*, 1988). These results suggest that interactions between heparin and thrombospondin may interfere with thrombospondin-induced smooth muscle cell proliferation and that the observed increases in VSMC proliferation following heparinase treatment may result, at least in part, from the removal of such inhibitory interactions. It has also been proposed that the effects of heparin on VSMC may result from its regulation of TGF- $\beta$ , an inhibitor of VSMC proliferation; heparin increases TGF- $\beta$  activation, and heparin-mediated antiproliferative effects are blocked by addition of a TGF- $\beta$  antibody. As such, heparinase treatment may prevent TGF- $\beta$  activation, abolishing the antiproliferative effects and explaining the conditioned media results. However, if heparin's effects are mediated by the inhibition of thrombospondin or activation of TGF- $\beta$ , one would expect that treatment of the endothelial-cell-conditioned medium with proteases should also eliminate the antiproliferative effect. However, the protease treatment does not prevent these effects; it is likely that heparin-like molecules also have a direct antiproliferative effect.

The possibility that certain ECM molecules may exert antiproliferative effects is further supported by various studies performed in culture. For example, normal human breast cells do not growth arrest when cultured on plastic, but they do so if grown in a basement membrane matrix (Petersen *et al.*, 1992; Weaver *et al.*, 1997). Furthermore, growth of a mammary epithelial cell line is stimulated by overexpression of Id-1, a protein that binds to and inhibits the function of basic helix-loop-helix (HLH) transcription factors, which are important in cell differentiation. However, when these Id-1-overexpressing cells are cultured on EHS, they arrest growth and assume a normal 3D structure (Desprez *et al.*, 1995; Lin *et al.*, 1995). Similarly, EHS suppresses the growth of cultured hepatocytes, apparently due to the decreased expression of immediate-early growth response genes and the concomitant increased levels of C/EBP $\alpha$ , which is necessary for the expression of hepatocyte-specific genes and also for growth arrest (Rana *et al.*, 1994).

Growth factors are critical in stimulation of cell proliferation. Indeed it has been found that some of the ECM

effects on cell proliferation involve cooperation with growth factors. bFGF, IL-1, IL-2, IL-6, hepatocyte growth factor, PDGF-AA, and TGF $\beta$  are found in association with ECM at high concentrations and are released at specific times for interaction with their receptors (Schonherr and Hausser, 2000). In the case of TGF $\beta$ , cooperation with the ECM occurs during the early developmental stages of the mammary gland during puberty (virgin gland; Daniel *et al.*, 1996). During this period, inductive events take place between the epithelium and the surrounding mesenchyme that are mediated by the basement membrane (basal lamina and closely associated ECM molecules) and that play an important role in epithelial proliferation during branching of the gland. Endogenous TGF $\beta$  produced by the ductal epithelium and surrounding mesenchyme forms complexes with mature periductal ECM. This TGF- $\beta$  may participate in stabilizing the epithelium by inhibiting both cell proliferation and the activity of matrix-degrading enzymes. However, TGF $\beta$  is absent from newly synthesized ECM deposited in the branching areas; thus its inhibitory effects on epithelial cell proliferation and on production of matrix-degrading enzymes do not occur, allowing the basement membrane to undergo remodeling. In these regions, proteases that are released locally partially degrade the matrix, thereby promoting cell proliferation and branching morphogenesis. An example of a protease important in this process is MMP-3/stromelysin-1, a protease important in basement membrane degradation and tissue remodeling; in mice transgenic for the autoactivated isoform of the MMP-3, the virgin glands are morphologically similar to the pregnant glands of normal mice (Sympson *et al.*, 1994). Furthermore, growth factor-induced branching morphogenesis in primary mammary organoids was shown to be MMP dependent, and application of recombinant MMP-3 to these organoids promoted morphogenesis in the absence of exogenous factors (Simian *et al.*, 2001). Taken together, these results suggest that MMP-3 stimulates the precocious proliferation of the epithelium and development of the alveoli due to the release of growth factors following matrix degradation.

### Differentiation

Processes leading to differentiation of keratinocyte, hepatocyte, and mammary gland epithelium illustrate well how ECM can affect cell behavior. Keratinocytes form the stratified epidermal layers of the skin. The basal layer is highly proliferative, does not express the markers for terminal differentiation, and is the only cell layer in contact with the basement membrane. As these cells divide, the daughter cells lose contact with the basement membrane, move up to the suprabasal layers, and begin to express differentiation markers, such as involucrin (Fuchs and Raghavan, 2002). This suggests that physical interaction with the basement membrane is responsible for the less differentiated basal keratinocytes. Indeed, it was first shown by Howard Green in 1977 that keratinocytes grown in suspension undergo

premature terminal differentiation. It has also been shown that human and mouse keratinocytes adhere to fibronectin via its  $\alpha_5\beta_1$  integrin receptor and that the expression of both is inversely proportional to the expression of involucrin, a differentiation marker for these cells (Nicholson and Watt, 1991). However, the role of keratinocyte adhesion to the basement membrane in the regulation of differentiation status is unclear, for the keratinocytes of a conditional integrin  $\beta_1$  skin knockout mouse do not undergo premature terminal differentiation, suggesting that further studies are necessary to better understand the contribution of the basement membrane in differentiation. A major advance in such studies has been the ability to culture keratinocytes on feeder layers of 3T3 cells or collagen gels containing human dermal fibroblasts, which then form stratified sheets of cells that behave very much like epidermis does *in vivo* (Green, 1977; Schoop *et al.*, 1999). This latter development has had profound application in treating patients that have suffered extensive burns (Ehrenreich and Ruszczak, 2006).

Similarly, hepatocytes in culture remain differentiated and expressing liver-specific genes only when they are grown in the presence of extracellular matrix molecules, such as EHS, laminin, or collagen I. This process appears to involve  $\alpha_3$  integrin; down-regulation of this integrin using antisense RNA decreases hepatocyte adhesion to laminin and collagen I and prevents the differentiation-specific effects mediated by collagen-I (Lora, 1998). The specific mechanisms whereby these cell-ECM interactions regulate differentiation have not been fully elucidated. However, three liver-specific transcription factors, eE-TF, eG-TF/HNF3, and eH-TF, are activated when cells are cultured on or with matrix molecules, conditions that favor hepatocyte differentiation. In particular, the transcription factor eG-TF/HNF3 appears to be regulated by ECM (DiPersio *et al.*, 1991).

In the mouse mammary gland, the basement membrane and its individual components, in conjunction with lactogenic hormones, are responsible for the induction of the differentiated phenotype of the epithelial cells. When midpregnant mammary epithelial cells are cultured on plastic, they do not express mammary-specific genes. However, when the same cells are plated and maintained on EHS, they form alveolar-like structures and exhibit the fully differentiated phenotype with expression of the genes encoding milk proteins (e.g., Nelson and Bissell, 2005). Cultures of single mammary epithelial cells inside EHS showed that the molecules involved in induction of the differentiated phenotype act via transmembrane receptors rather than involving cell polarity or growth factors. It was later found that laminin is the ECM molecule present in EHS that is ultimately responsible for the observed differentiation and that the  $\beta_1$  integrin is critical in maintaining the differentiated state (Faraldo *et al.*, 2002; Nelson and Bissell, 2005). The impact of ECM molecules on the expression of milk

proteins may be indirect, by altering the secretion of a growth factor that then affects milk protein, or more directly through signal transduction leading to changes in gene expression. An example of the former is seen in the stimulation of whey acidic protein (WAP) in mouse mammary gland epithelial cells. WAP expression is inhibited when cells are cultured on plastic; but if they are grown on ECM, expression is up-regulated. It has been found that cells cultured on plastic produce TGF $\alpha$ , which inhibits the expression of WAP, whereas the EHS matrix inhibits the production of TGF $\alpha$ , thus leading to the up-regulation of this milk protein (Lin *et al.*, 1995). An example that demonstrates the direct influence of ECM on the expression of milk protein genes comes from work performed on the expression of  $\beta$ -casein. It has been shown that there are two components to  $\beta$ -casein induction by ECM: One involves cell rounding (and therefore a change in the cytoskeleton) and the other a tyrosine kinase signal transduction pathway through integrin  $\beta_1$  and potentially also integrin  $\alpha_6\beta_4$ , leading to the activation of elements in the promoter region of the  $\beta$ -casein gene (Muschler *et al.*, 1999; Nelson and Bissell, 2005).

### Apoptosis

Programmed cell death occurs during embryogenesis of higher vertebrates in areas undergoing remodeling, such as in the development of the digits, palate, and nervous system, in the positive selection of thymocytes in the thymus, during mammary gland involution, and during angiogenesis. For example, basement membrane molecules appear to suppress apoptosis of the epithelial cells during the involution of the mammary gland (Strange *et al.*, 1992). The numerous alveoli that produce milk during lactation regress and are resorbed during involution due to enzymatic degradation of alveolar basement membrane and programmed cell death (Strange *et al.*, 1992; Talhouk *et al.*, 1992). During this involution, apoptosis appears to proceed in two distinct phases. An early phase characterized by increased expression of apoptosis-associated proteins, including interleukin-1 $\beta$ -converting enzyme (ICE), a protein known to be important in promoting mammary epithelial cell apoptosis (Boudreau *et al.*, 1995) is followed by a later apoptotic phase in which cell-ECM interactions are decreased due to both matrix degradation (Lund *et al.*, 1996) and reduced expression of integrin  $\beta_1$  and FAK (McMahon *et al.*, 2004). This disruption of cell-ECM binding is important for the apoptosis of mammary epithelial cells because ECM adhesion imparts critical survival signals. Indeed, these cells undergo apoptosis when an antibody is used to disrupt interactions between  $\alpha_1$  integrin and its ECM ligands (Boudreau *et al.*, 1995). Similarly, it has been found that  $\alpha_v\beta_3$  integrin interactions with ECM play a crucial role in endothelial cell survival during angiogenesis in embryogenesis. Disruption of these interactions with an antibody to  $\alpha_v\beta_3$  inhibits the development of new blood vessels in the chorioallantoic membrane (CAM) by causing the endothelial cells to undergo apoptosis

(Brooks *et al.*, 1994). In addition, tumstatin, a proteolytic fragment of collagen IV, induces endothelial cell apoptosis and thereby prevents angiogenesis via interaction with  $\alpha_v\beta_3$  (Maeshima *et al.*, 2001). This interaction may promote apoptosis by interfering with normal integrin-ECM binding, thus removing a critical survival signal. Tumstatin may also promote apoptosis through a separate mechanism, such as via the recruitment and activation of caspase 8, as has been suggested previously for such soluble ligands (Stupack *et al.*, 2001). All in all, these findings suggest that disruption of cell-ECM interactions may lead to an increase in the expression or activation of pro-apoptotic molecules, and may also lead to the removal of pro-survival signals, which then directly or indirectly cause apoptosis.

## Wound Healing

### Adhesion and Migration

Early in the wound-healing process, blood components and tissue factors are released into the wounded area in response to tissue damage, promoting both the activation and adhesion of platelets and the formation of a clot consisting of platelets, cross-linked fibrin, and plasma fibronectin as well as lesser amounts of SPARC (secreted protein acidic and rich in cysteine), tenascin, and thrombospondin. This is accompanied by the degranulation of mast cells, releasing factors important in vasodilation and in polymorphonuclear cell chemotaxis to the injured area, thereby initiating the inflammatory response. During these early stages of wound healing, a temporary extracellular matrix consisting of the fibrin-fibronectin meshwork facilitates the migration of keratinocytes to close the wound as well as the migration of leukocytes into the wounded area. Leukocyte adhesion, migration, and secretion of inflammatory mediators are further affected by their interactions with various ECM molecules (Vadady and Lider, 2000). Pro-inflammatory cytokine release from tissue macrophages, for example, occurs after CD44-mediated binding to low-molecular-weight hyaluronic acid (Hodge-Dufour *et al.*, 1997). As such, the types of ECM molecules present in the injured area may greatly affect the inflammatory phase of wound healing by influencing leukocyte behavior (Vadady and Lider, 2000). Furthermore, specific ECM molecules can bind chemokines, creating a stable gradient to promote leukocyte chemotaxis into the injured area. ECM-chemokine binding is critical for appropriate leukocyte recruitment, for mutant chemokines lacking the ability to bind glycosaminoglycans failed to induce chemotaxis *in vivo* (Handel *et al.*, 2005).

As mentioned earlier, keratinocytes participating in the re-epithelialization phase of cutaneous wound healing migrate on a provisional matrix composed of fibrin/fibrinogen, fibronectin, collagen type III, tenascin, and vitronectin. The keratinocytes express multiple receptors for these matrix molecules, including the integrins  $\alpha_2\beta_1$ ,  $\alpha_3\beta_1$ ,  $\alpha_5\beta_1$ ,  $\alpha_6\beta_1$ ,  $\alpha_5\beta_4$ , and  $\alpha_v$ ; cell migration and the subsequent wound

closure are facilitated by cell–ECM interactions via these receptors. The fibrin/fibrinogen meshwork appears to be of particular importance in re-epithelialization, as evidenced by the disordered re-epithelialization seen in fibrinogen-deficient mice (Drew *et al.*, 2001). This process also appears dependent on the synthesis and deposition of laminin, because keratinocyte migration on collagen and fibronectin was inhibited by an antilaminin antibody (Decline and Rousselle, 2001).

Interactions between epithelial cells and ECM are also critical in the wound closure of other types of epithelial wounds. After wounding, retinal pigment epithelial cells exhibit a sequential pattern of ECM molecule deposition that is critical in the epithelial cell adhesion and migration associated with wound closure. Within 24 hours of wounding, these epithelial cells secrete fibronectin, followed shortly by laminin and collagen IV. If the cell adhesion to these ECM molecules is blocked with either cyclic peptides or specific antibodies, the epithelial cells fail to migrate and close the wound, underscoring the importance of such interactions in wound closure (Hergott *et al.*, 1993; Hoffmann *et al.*, 2005). Similarly, the inhibition of various integrins or fibronectin in airway epithelial cells following mechanical injury largely prevented cell migration and wound healing.

During later stages of wound healing, macrophages and fibroblasts in the injured area deposit embryonic-type cellular fibronectin, which is important in the generation of the granulation tissue, a temporary connective tissue consisting of multiple types of ECM molecules and newly formed blood vessels (Li *et al.*, 2003). The cellular fibronectin provides a substrate for the migration of endothelial cells into the granulation tissue, thus forming the wound vasculature, and also facilitates the chemotaxis of myofibroblasts and lymphocytes stimulated by a variety of chemotactic cytokines (chemokines) that are produced by tissue fibroblasts and macrophages (Greiling and Clark, 1997; Feugate *et al.*, 2002). Many chemokines have been characterized in multiple species, including humans, other mammals, and birds, and have been grouped into a large superfamily that is further subdivided based on the position of the N-terminal cysteine residues (Gillitzer and Goebeler, 2001). These chemokines, along with cell–ECM interactions, are critical for the adhesion and chemotaxis/migration of the cells that ultimately enter the wounded area and generate the granulation tissue (Martins-Green and Feugate, 1998; Feugate *et al.*, 2002).

One prototypical chemokine, IL-8, has several functions important in wound healing. These functions have largely been elucidated in studies performed in the chick model system using chicken IL-8 (cIL-8/cCAF) (Martins-Green, 2001). After wounding, fibroblasts in the injured area produce large quantities of cIL-8, most likely resulting from their stimulation by thrombin, a coagulation enzyme activated on wounding that is known to induce fibroblasts to

express and secrete cIL-8. The initial rapid increase in IL-8 generates a gradient that attracts neutrophils (Martins-Green, 2001). These cells, in turn, produce monocyte chemoattractant protein, a potent chemottractant for monocytes that differentiate into macrophages when in the wound environment. In addition, our *in vitro* studies using human THP-1-derived macrophages show that these cells can be stimulated to produce high levels of IL-8 (Zheng and Martins-Green, 2006), further increasing the levels of this chemokine in the wound tissue and potentially leading to angiogenesis. IL-8 is also secreted by the endothelial cells of the wound vasculature and is capable of binding to various matrix components of the granulation tissue, further increasing the presence of IL-8 in the granulation tissue. Therefore, IL-8 not only functions in the inflammatory phase of wound healing by serving as a leukocyte chemoattractant, but also plays an important role in granulation tissue formation by stimulating angiogenesis and matrix deposition (Martins-Green, 2001; Feugate *et al.*, 2002). Angiogenesis occurring during granulation tissue formation relies heavily on cell–ECM interactions, as mentioned earlier under “Development.”

### Proliferation

After wounding, the keratinocytes alter their proliferation and migration in order to close the wound, a process known as *re-epithelialization*. As this process occurs, the cells at the edge of the wound migrate, whereas the cells around the wound proliferate in order to provide the additional cells needed to cover the wounded area. The proliferative state of these latter keratinocytes may be sustained by interactions with the ECM of the remaining basement membrane. Indeed, during the remodeling of normal skin, the proliferation of the basal layer of keratinocytes needed to replace the upper keratinocyte layers requires the presence of fibronectin in the epithelial basal lamina (see earlier). In addition, in a dermal wound model, ECM derived from the basement membrane can maintain the keratinocytes in a proliferative state for several days. It is likely that, in addition to fibronectin, laminin participates in keratinocyte proliferation, because previous work indicates that laminin can promote proliferation of these cells *in vitro* (Pouliot *et al.*, 2002). On the other hand, fibrin present in the provisional matrix may have an inhibitory effect on keratinocyte proliferation, as evidenced by the abnormal keratinocyte proliferation seen during the re-epithelialization of fibrinogen-deficient mice (Drew *et al.*, 2001).

The granulation tissue begins to form as re-epithelialization proceeds. This tissue is composed of ECM molecules, including embryonic fibronectin, type III collagen, type I collagen, and hyaluronic acid, along with multiple cell types, such as monocyte/macrophages, lymphocytes, fibroblasts, myofibroblasts, and the endothelial cells of the wound vasculature. Growth factors released by these cells and platelets cooperate with the aforementioned

surrounding ECM molecules, to provide pro-proliferative signals to the granulation tissue fibroblasts and endothelial cells. In the case of endothelial cells, the increased proliferation can participate in the formation of the wound vasculature via angiogenesis. In this process, ECM molecules interact with VEGFs and FGFs, angiogenic factors that then stimulate endothelial cell proliferation and migration to form new blood vessels (Sottile, 2004). The importance of ECM-growth factor binding in blood vessel formation is underscored by recent studies suggesting that the antiangiogenic molecules thrombospondin and endostatin may exert their antiangiogenic effects by competing with proangiogenic growth factors for ECM binding (Gupta *et al.*, 1999; Reis *et al.*, 2005). Furthermore, some growth factors appear to promote proliferation only when specific ECM molecules are present, as is seen in the fibronectin requirement for TGF- $\beta$ 1-mediated fibroblast proliferation (Clark *et al.*, 1997). In contrast, VEGF is unable to induce proliferation when bound to SPARC, indicating that interactions between growth factors and ECM can also be inhibitory (Kupprion *et al.*, 1998). While ECM-growth factor interactions can significantly impact cell proliferation, specific ECM molecules also affect proliferation directly. Fibronectin, specific fragments of fibronectin, laminin, collagen VI, and SPARC/osteonectin can directly induce fibroblast and endothelial cell proliferation (e.g., Ruhl *et al.*, 1999; Sage *et al.*, 2003; Sottile, 2004). Previous studies suggest that the proliferative ability of laminin is mediated by its EGF-like domains, implicating EGFR activation in its pro-proliferative effects (Panayotou *et al.*, 1989; Schenk *et al.*, 2003). In addition, certain ECM molecules and/or proteolytic fragments can inhibit proliferation. SPARC and decorin as well as peptides derived from SPARC, decorin, collagen IV (tumstatin), and collagens XVIII and XV (endostatin) are antiangiogenic due to their inhibitory effects on endothelial cell proliferation (Sage *et al.*, 2003; Sottile, 2004; Sulochana *et al.*, 2005).

### Differentiation

As the granulation tissue forms, some of the fibroblasts within the wounded area differentiate into myofibroblasts, cells that express the protein  $\alpha$ -smooth muscle actin ( $\alpha$ SMA) and thus function similarly to smooth muscle cells (Desmouliere *et al.*, 2005). This differentiation process is influenced by various matrix molecules, such as heparin, which decreases fibroblast proliferation while stimulating  $\alpha$ SMA expression *in vitro*. Similarly, although the *in vivo* application of tumor necrosis factor  $\alpha$  (TNF $\alpha$ ) promotes granulation tissue formation, myofibroblasts were only detected when heparin was also added (Desmouliere *et al.*, 1992). The effects of heparin on myofibroblast differentiation and  $\alpha$ SMA expression are probably not due to its anticoagulant activity, but more likely result from the ability of heparin and heparan sulfate proteoglycans to interact with cytokines and/or growth factors such as TGF- $\beta$ 1, which then modulate myofibroblast differentiation (Li *et al.*, 2004). This

TGF- $\beta$ 1-induced differentiation is prevented when  $\alpha_v$  or  $\beta_1$  integrins or the ED-A-containing form of fibronectin are inhibited (Lygoe *et al.*, 2004; Desmouliere *et al.*, 2005). Furthermore, cardiac fibroblasts differentiate into myofibroblasts after plating on collagen VI (Naugle *et al.*, 2006). Interstitial collagens, in conjunction with mechanical tension, also participate in the differentiation process. Fibroblasts cultured on collagen-coated plates or relaxed collagen gels fail to differentiate, whereas fibroblasts cultured under conditions that more closely mimic the granulation tissue, on anchored collagen gels with aligned collagen fibers, exhibit myofibroblast characteristics (Arora *et al.*, 1999). In addition, more recent observations *in vitro* and during wound healing *in vivo* have further established a role for mechanical tension in myofibroblast differentiation (Wang *et al.*, 2003).

### Apoptosis

Late in the wound-healing process, the granulation tissue undergoes remodeling to form scar tissue. This remodeling phase is characterized by decreased tissue cellularity due to the disappearance of multiple cell types, including fibroblasts, myofibroblasts, endothelial cells, and pericytes, and by the accumulation of ECM molecules, particularly interstitial collagens. The observed reduction in cell numbers during the remodeling phase occurs due to apoptosis. The number of apoptotic cells in the granulation tissue was shown to increase 20–25 days after wounding, with the significant decrease in cellularity apparent after 25 days (Desmouliere *et al.*, 1995). Many of these apoptotic cells are endothelial cells and myofibroblasts, as shown by studies using *in situ* DNA fragment end-labeling in conjunction with transmission electron microscopy. Moreover, the release of mechanical tension in a system mimicking the formation of granulation tissue and its subsequent regression stimulates human fibroblast and myofibroblast apoptotic cell death. The apoptosis observed in this system was regulated by a combination of growth factors and the mechanical tension exerted by contractile collagens, underscoring the importance of such collagens in regulating apoptosis within the healing tissue. The fibroblast apoptosis regulated by mechanical tension also appears to involve interactions between thrombospondin-1 and the  $\alpha_v\beta_3$  integrin-CD47 complex (Graf *et al.*, 2002). Apoptosis of fibroblasts and myofibroblasts may be important in preventing excessive scarring and facilitating the resolution of wound healing. Indeed, in keloids and hypertrophic scars there is a decrease in apoptosis of these cells, leading to increased matrix deposition and scarring. In keloids, the lack of apoptosis is thought to be caused by mutations in p53 or by growth factor receptor overexpression (e.g., Ladin *et al.*, 1998; Ishihara *et al.*, 2000; Moulin *et al.*, 2004). In hypertrophic scars, however, the reduced apoptosis may result from increased expression of tissue transglutaminase, resulting in enhanced matrix degradation and diminished

collagen contraction (Linge *et al.*, 2005). There is also evidence to suggest that alternative types of cell death may have roles in wound healing. For example, bronchoalveolar lavage fluid collected after lung injury during the remodeling phase stimulated fibroblast death in a manner that is not consistent with either apoptotic or necrotic cell death (Polunovsky *et al.*, 1993).

### III. SIGNAL TRANSDUCTION EVENTS DURING CELL-ECM INTERACTIONS

As discussed earlier, ECM molecules are capable of interacting with a variety of receptors. Such interactions activate signal transduction pathways within the cell, altering levels of both gene expression and protein activation, thus ultimately changing outcomes in cell adhesion, migration, proliferation, differentiation, and death. The signaling pathways linked to these specific outcomes have been studied for many of the ligand–receptor interactions, particularly those involving integrins. Based on these studies, we postulate the existence of three categories of cell–ECM interactions that lead to the aforementioned cellular events (Fig. 7.2).

#### Type I Interactions

These are generally mediated by integrin and proteoglycan receptors and are important in the adhesion/deadhesion processes that accompany cell migration (Fig. 7.2A). These interactions are exemplified by fibronectin-mediated cell migration, which occurs when this matrix molecule simultaneously binds integrins and proteoglycans, the latter via its heparin-binding domain (Dedhar, 1999; Mercurius and Morla, 2001). These fibronectin receptors then colocalize and interact at cell adhesion sites, where the microfilaments interact with the cytoplasmic domain of integrin  $\beta_1$  through the structural proteins talin and  $\alpha$ -actinin. The fact that integrins interact with the cytoskeleton suggests that the integrin-induced signaling involved in adhesion and migration may be mediated, in part, by the cytoskeleton itself. Additional integrin-mediated signaling occurs via the

activation of the focal adhesion tyrosine kinase pp125<sup>FAK</sup>, which also interacts with the cytoplasmic domain of integrin  $\beta_1$ . On activation, pp125<sup>FAK</sup> phosphorylates itself at tyrosine 397 (Hildebrand *et al.*, 1995), which then serves as the binding site for the SH2 domain of the c-Src tyrosine kinase. This kinase subsequently phosphorylates multiple proteins present in the focal adhesion plaques, including FAK itself, at position 925, as well as paxillin, tensin, vinculin, and p130<sup>cas</sup>. FAK phosphotyrosine 925 binds the Grb2/Sos complex, thus promoting the activation of Ras GTPase and the MAP kinase cascade, which may be involved in cell adhesion/deadhesion and migration events (Schlaepfer and Hunter, 1998; Dedhar, 1999). Paxillin may also participate in integrin-mediated signaling and motility, as evidenced by the reduced migration and decreased phosphorylation/activation of various signaling molecules observed in paxillin-deficient fibroblasts (Hagel *et al.*, 2002). The contribution of tensin to cell adhesion and motility is poorly understood, although it is known to interact with the cytoskeleton and various phosphorylated signaling molecules via its SH2 domain. Therefore, tensin may facilitate various signaling events downstream of integrin ligation (Lo, 2004). Active p130<sup>cas</sup> interacts with Crk and Nck, which function as adaptor molecules that appear to increase cell migration by promoting the localized activation of Rac-GTPase and the MAP/JNK kinase pathways (Chodniewicz and Klemke, 2004).

#### Type II Interactions

These involve processes in which the matrix–receptor interactions, in conjunction with growth factor or cytokine receptors, affect proliferation, survival, differentiation, and/or maintenance of the differentiated phenotype (Fig. 7.2B). These cooperative effects may occur in a direct manner, for example, by the direct interaction of EGF-like repeats present in certain ECM molecules with the EGF receptor, thereby promoting cell proliferation (Swindle *et al.*, 2001; Tran *et al.*, 2004). Indirect cooperative effects are better understood at this time, particularly with regard to the

**FIG. 7.2.** Schematic diagrams illustrating the three categories of cell/ECM interactions proposed here. These categories are represented by sketches of the binding elements. **(A) Type I interactions** are generally mediated by integrin and proteoglycan receptors and are important in the adhesion/deadhesion processes that accompany cell migration. At focal adhesions, proteoglycan (treelike) and integrin (heterodimer) receptors on the plasma membrane (pm) bind to different epitopes on the same ECM molecule, leading to cytoskeletal reorganization. A variety of proteins become phosphorylated (e.g., pp125<sup>FAK</sup> and src), leading to activation of genes important for cell adhesion/deadhesion and for migration. **(B) Type II interactions** involve processes in which matrix–receptor interactions, in conjunction with growth factor or cytokine receptors, affect proliferation, survival, differentiation, and/or maintenance of the differentiated phenotype. Integrin receptors bind to their ligands, leading to activation of cytoskeletal elements as in Type I; but, also, growth factors bound to matrix molecules (triangle) bind to their receptors, which have kinase activity. This kinase activates phospholipase C $_{\gamma}$ , which, in turn, cleaves PIP $_2$ , leading to inositoltrisphosphate (IP $_3$ ) and diacylglycerol (DAG); IP $_3$  binds to its receptor on the smooth endoplasmic reticulum, inducing the release of Ca $^{++}$ , which can lead directly to activation of gene expression or indirectly by cooperation with DAG through protein kinase C (PKC). In this case, the genes activated are important in cell proliferation, differentiation and maintenance of the differentiated phenotype. **(C) Type III interactions** involve mostly processes leading to apoptosis and epithelial-to-mesenchymal transitions. Integrin receptors bind to fragments of ECM molecules containing specific domains. This leads to activation of matrix protease genes whose products (represented by purple ellipses) degrade the matrix and release peptides (squiggles) that can further interact with cell surface receptors and/or release growth factors (triangles and diamonds), which, in turn, bind to their own receptors, activating G proteins and kinases leading to expression of genes important in morphogenesis and cell death.

anchorage dependence of cell growth. S-phase entry, even when growth factors are present, requires the interaction of cells with a substrate, underscoring the critical role of cell-ECM adhesion in cell survival and proliferation (Giancotti, 1997; Hynes, 2002). Specifically, integrin ligation promotes the activation of Fyn and its binding to the Shc adaptor protein, which then recruits Grb2, thus activating the Ras/ERK pathway, resulting in the phosphorylation of the transcription factor Elk-1 and the activation of genes important in cell cycle progression. Furthermore, cell-ECM interactions are critical for the efficient and prolonged activation of MAPK by growth factors (Howe *et al.*, 2002). Ras-mediated signaling also leads to the activation of PI-3 kinase and thus of the Akt serine/threonine kinase; the activation of this pathway prevents the apoptosis of suspended cells. Integrin ligation also appears to promote cell proliferation through the degradation of cell cycle inhibitors, as is seen in the degradation of p21 downstream of fibronectin-mediated Cdc42 and Rac-1 activation. The critical role of the Rac/JNK pathway in this process is also seen in the  $\beta_1$  integrin cytoplasmic domain mutant, in which the decreased activation of this pathway was correlated with diminished fibroblast proliferation and survival. Both of these effects were reversed on the expression of constitutively active Rac1 (Hirsch *et al.*, 2002). Negative affects on cell proliferation were also observed in other studies, in which integrins were inhibited or knocked out. For example, fibroblasts derived from mice lacking the  $\alpha_5\beta_1$  integrin proliferated at a reduced rate, despite the fact that they were able to attach normally (Pozzi *et al.*, 1998). A similar result was seen in mammary epithelial cells overexpressing a dominant negative  $\beta_1$  integrin subunit (Faraldo *et al.*, 2001).

Similarly, cellular differentiation also relies on cell interactions with ECM molecules, hormones, and growth factors, particularly those interactions that do not activate Shc and the MAP kinase cascade. For example, the binding of laminin to integrin  $\alpha_2\beta_1$  in endothelial cells fails to activate the Shc pathway and promotes the formation of capillary-like structures (Kubota *et al.*, 1988), whereas the binding of fibronectin to integrin  $\alpha_5\beta_1$  in these cells leads to cell proliferation (Wary *et al.*, 1998). Additional signaling molecules are required to generate these capillary-like tubes. One such molecule is integrin-linked kinase (ILK), which, when overexpressed, rescues capillary-like tube formation in the absence of ECM molecules (Cho *et al.*, 2005), while expression of a dominant negative version of ILK blocks tube formation even when ECM and VEGF are present (Watanabe *et al.*, 2005). Integrin-mediated signaling is also important in other differentiated phenotypes, e.g., in the differentiation of myofibroblasts, cells important in wound healing; the myofibroblast differentiation induced by TGF- $\beta_1$  is dependent on specific integrin ligation as well as the activation of FAK and its associated signaling pathways (Thannickal *et al.*, 2003; Lygoe *et al.*, 2004).

### Type III Interactions

These primarily involve processes leading to apoptosis and epithelial-to-mesenchymal transitions (Fig. 7.2C). Apoptotic pathways have been identified for endothelial cells and leukocytes and appear to involve primarily tyrosine kinase activity (Ilan *et al.*, 1998; Avdi *et al.*, 2001). For example, neutrophil apoptosis stimulated by TNF- $\alpha$  is dependent on  $\beta_2$  integrin-mediated signaling events involving the activation of the Pyk2 and Syk tyrosine kinases as well as JNK1 (Avdi *et al.*, 2001). In other cell types, alterations in the ligand presentation by ECM can also regulate apoptosis. Studies have suggested that integrin ligation by soluble, rather than intact, ligands can function as integrin antagonists and promote apoptosis rather than survival or proliferation (Stupack and Chersesh, 2002). Such soluble ligands may be created by matrix degradation during tissue remodeling. The apoptosis stimulated by soluble ligands or other antagonists appears to occur via the recruitment and activation of caspase 8 by clustered integrins, without any requirement for death receptors. In such cases, matrix remodeling is critical, because enzymatic degradation of the ECM causes the release of both soluble factors as well as ECM fragments that contain specific sequences that affect cell behavior and/or exhibit altered receptor interactions. For example, when fibronectin binds only through its cell-binding domain, the cells are stimulated to produce ECM-remodeling enzymes. There are at least three possible ways in which such a process could be initiated. (1) Changes in expression of fibronectin receptors would allow cells to bind fibronectin, predominantly through its cell-binding domain, and activate  $\alpha_5\beta_1$  interactions with the actin cytoskeleton, with subsequent transduction of signals that lead to up-regulation of ECM-degrading enzymes. The secretion of these enzymes would start a positive-feedback loop by degrading additional fibronectin to produce cell-binding fragments that would bind to  $\alpha_5\beta_1$ , activate it, and in this way keep the specific event going. (2) Very localized release of ECM-degrading enzymes could degrade fibronectin into fragments containing only the cell-binding domain, which would bind to  $\alpha_5\beta_1$  and initiate the positive-feedback loop. (3) At a particular time during development, specific cells would produce spliced forms of fibronectin that are only capable of interacting via their cell-binding domain. Binding of these fragments to  $\alpha_5\beta_1$  would trigger the feedback loop. This positive-feedback loop and consequent runaway process of ECM degradation is advantageous locally for such events as cell growth, epithelial-to-mesenchymal transitions, or cell death, relieving their tight regulation. However, during normal development and wound healing, there must be a signal that can break this cycle and thereby bring it under control at the appropriate time and place. Without application of such a brake, these processes can lead to abnormal development or wound

healing or to pathological situations, such as tumor growth and invasion.

Although these three categories may not be exhaustive of the general types of cell–ECM interactions that occur during development and wound healing, they encapsulate the major interactions documented to date. Each category has its place in many developmental and repair events, and they may operate in sequence. A compelling example of the latter is the epithelial-to-mesenchymal transition and morphogenesis of the neural crest cell system (Martins-Green and Bissell, 1995). These cells originate in the neural epithelium that occupies the crest of the neural folds. After the delamination event that separates the neural epithelium from the epidermal ectoderm (Martins-Green, 1988), the folds fuse to form the tube. At this time, the NCC occupy the dorsalmost portion of the tube, they are not covered by basal lamina, and the subepidermal space above them contains large amounts of fibronectin (Martins-Green and Erickson, 1987). Just before the NCC emigrate from the neural tube, fibronectin appears between them; they separate from each other and migrate away, carrying fibronectin on their surfaces (Martins-Green, 1987). During the period of emigration at any particular level of the neural tube, basal lamina is deposited progressively toward the crest from the sides of the tube (Martins-Green and Erickson, 1986, 1987). NCC emigration terminates as deposition reaches the crest of the tube. The NCC then follow specific migration pathways throughout the embryo, arriving at a wide variety of locations, where they differentiate into many different phenotypes in response to external cues (Perris and Perissinotto, 2000).

The appearance of fibronectin between the NCC just before emigration must be the result of secretion by the adjacent cells or introduction from the epithelial cells after loss of cell–cell adhesions. In keeping with the cell–ECM interaction mechanism of Type III, either alternative could initiate a positive-feedback loop and release the NCC, leading to emigration. Enzymatic degradation of the stabilizing domain of fibronectin above the tube could cause enhanced secretion of specific enzymes by the NCC in response to the effect of the cell-binding domain acting alone, thus severing the cell adhesions and producing additional fibronectin fragments containing the cell-binding domain. These fragments, in turn, would bind to adjacent cells and stimulate further enzymatic secretion that would be self-perpetuating. NCC emigration occurs in an anterior-to-posterior wave; thus, following initiation of enzymatic activity in the head of the embryo, it could propagate in a posterior direction, triggering NCC emigration in a wave from head to tail.

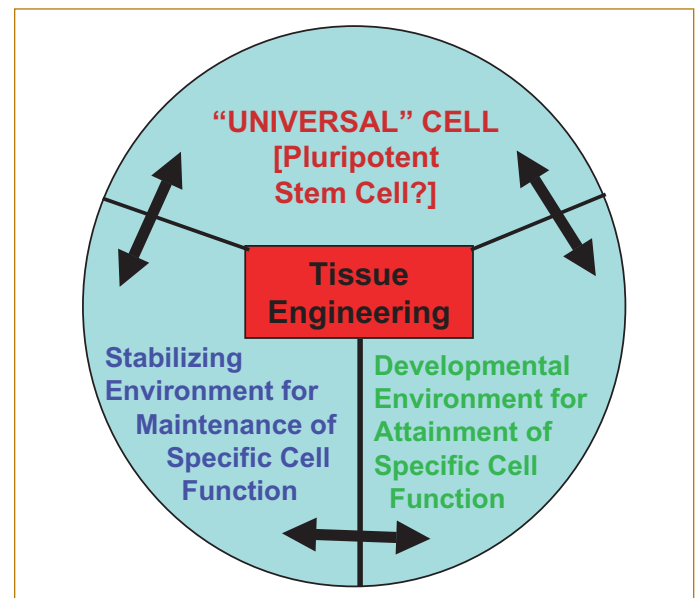

Clearly some controlling event(s) must terminate NCC emigration at each location along the neural tube. Such an event has already been identified. At the time of NCC emigration, the ventral and lateral surfaces of the neural tube

are covered by an intact basal lamina, which stabilizes the epithelium and separates it from the fibronectin layer around the tube (Martins-Green and Erickson, 1986). During the few hours of emigration at any one site, as the NCC are leaving from the dorsalmost portion of the neural tube, basal lamina deposition progresses quickly up the sides of the tube and terminates local emigration when it becomes complete over the crest of the tube (Martins-Green and Erickson, 1986, 1987). After they have emigrated from the neural tube, the NCC find themselves in an extracellular space filled with intact fibronectin and other ECM molecules that stimulate the focal adhesions of cell–ECM interactions of Type I, thereby providing the substrate for migration. On arrival at their final destination, further interactions of Type II stimulate differentiation into a wide range of phenotypes (Perris and Perissinotto, 2000).

#### IV. RELEVANCE FOR TISSUE ENGINEERING

Designing tissue and organ replacements that closely simulate nature is a challenging endeavor. One avenue to achieve this goal is to study how tissues and organs arise during embryogenesis and during normal processes of repair and how those functions are maintained. When developing tissue replacements, one needs to consider the following (Fig. 7.3).

1. *Avoiding an immune response that can cause inflammation and/or rejection.* Ideally, one would like to manipu-

**FIG. 7.3.** Conceptualization of the interactions of a “universal” cell, i.e., a pluripotent stem cell, and environments in which it is conditioned to a particular function (developmental environment) and maintained in that function (stabilizing environment).

late cells *in vitro* to make them more universal and thereby decrease the possibility of immune responses. In theory, these cells could then differentiate in the presence of an environment conducive to expression of the appropriate phenotype. However, little progress has been made toward this elusive goal. Alternatively, engineered tissues could incorporate progenitor cells that may suppress host immune responses directly or indirectly through decreased expression of MHC; these cells could be induced at a later time to differentiate into various cell types (Barry and Murphy, 2004). One example of a progenitor cell that appears to decrease immune responses and also maintains a broad differentiation capacity is the mesenchymal stem cell, which is capable of differentiating into multiple cell types and may thus prove to be an invaluable asset in tissue engineering (Barry and Murphy, 2004).

2. *Creating the proper substrate for cell survival and differentiation.* One of the strategies to fulfill this goal is the use of biocompatible implants composed of extracellular matrix molecules seeded with autologous cells or with heterologous cells in conjunction with immunosuppressant drugs. Addition of growth and differentiation factors to these matrices as well as agonists or antagonists that favor cell-ECM interactions can potentially increase the rate of successful tissue replacement. One example in which the knowledge obtained in studies of cell-ECM interactions has proven useful in tissue engineering was the discovery that most integrins bind to their ECM ligands via the tripeptide RGD. This small sequence of amino acids has been used as an agonist to make synthetic implants more biocompatible and to allow the development of tissue structure or as an antagonist to prevent or moderate unwanted cell-ECM interactions. An example of the latter is the use of RGD-containing peptides to prevent fibrinogen interaction and thus modulate platelet aggregation and formation of thrombi during reconstructive surgery or in vascular disease (Bennett, 2001). Similarly, collagen has been used to coat synthetic biomaterials to increase their biocompatibility and promote successful biological interactions (Ma *et al.*, 2005). While the foregoing examples show that ECM molecules can be used successfully in tissue engineering, the use of natural ECM molecules in engineered tissue has several disadvantages, including the possibility of generating an immune response, possible contamination, and ease of degradation. Likewise, artificial biocompatible materials have significant drawbacks, in that, unlike ECM, they are generally incapable of transmitting growth and differentiation cues to cells (e.g., Rosso *et al.*, 2005). One future alternative to these approaches may be preparation of “semisynthetic biomaterials,” in which func-

tional regions of ECM molecules, including those that interact with receptors or growth factors or those that are cleaved by proteases, are incorporated into artificial biomaterials to impart additional functionality (Lutolf and Hubbell, 2005; Rosso *et al.*, 2005). The inclusion of ECM-like cell-binding sites that promote cell adhesion, growth, and/or differentiation into such biomaterials may be critical in developing and maintaining functional engineered tissues by providing the appropriate cellular microenvironment. However, the use of either native ECM molecules or engineered ECM-like biomaterials in engineered tissues requires additional knowledge regarding the types of cell-ECM interactions that result in the desired cellular effects.

3. *Providing the appropriate environmental conditions for tissue maintenance.* To maintain tissue homeostasis, it is crucial to create a balanced environment with the appropriate cues for preservation of specific cell function(s). It is important to realize that such stasis on the level of a tissue is achieved via tissue remodeling — the *dynamic equilibrium* between cells and their environment. However, little is known about the cross-talk between cells and ECM under such “normal” conditions. As indicated earlier, the same ECM molecule may have multiple cellular effects. The ultimate cellular outcome likely depends on the combination of variables, such as the domain of the molecule involved in the cellular interactions, the receptor used for these interactions, and the cellular microenvironment. These variables can, in turn, be influenced by matrix remodeling, because enzymatic degradation of the ECM can release functional fragments of ECM that then alter cell-ECM interactions by removing certain binding sites while exposing others.

Because organ transplantation is one of the least cost-effective therapies and is not always available, tissue engineering offers hope for more consistent and rapid treatment of those in need of a body part replacement, and it therefore has greater potential to improve patient quality of life. The selected examples presented illustrate that further advances in tissue engineering require additional knowledge of the basic mechanisms of cell function and of the ways they interact with the environment. The recent surge in research on ECM molecules themselves and their interactions with particular cells and cell surface receptors has led to realization that these interactions are many and complex, allow the modulation of fundamental events during development and wound repair, and are crucial for the maintenance of the differentiated phenotype and tissue homeostasis. As such, the manipulation of specific cell-ECM interactions has the potential to modulate particular cellular functions and processes in order to maximize the effectiveness of engineered tissues.

### I. INTRODUCTION

Successful repair, regeneration or replacement of tissues and organs by tissue engineering requires insights into the processes, tested and refined during a billion years of evolution, by which cells form, maintain, and repair tissues. It is based on understanding what goes on inside cells as well as knowledge about what goes on between them; how they generate their extracellular matrix (ECM) environment; how they fill it with molecules that allow them be buffered against mechanical and chemical stress; how they use it to communicate with each other and to proliferate, differentiate, migrate, and survive within it. This chapter describes some of the major classes of molecules that allow the ECM to meet the needs of the cells within it. It describes polymer-forming proteins such as collagen, elastin, and fibrillin that allow cells to be organized in space and provide the basis for spatially defined interactions between cells. It discusses adhesive glycoproteins that bind to integrins and other cell surface receptors regulating attachment, shape, proliferation, and differentiation of cells. It further describes large proteoglycans that generate hydrophilic tissue compartments for both facilitating and blocking of cell migration. Finally, it provides examples of how matrix molecules, in addition to serving in structural roles, can regulate cell

behavior by stimulating and inhibiting growth factor activities or by releasing peptide fragments that act directly on cells.

Cellular growth and differentiation, in two-dimensional cell culture as well as in the three-dimensional space of the developing organism, requires the presence of a structured environment with which the cells can interact. This extracellular matrix (ECM) is composed of polymeric networks of several types of macromolecules in which smaller molecules, ions, and water are bound. The major types of macromolecules are polymer-forming proteins, such as collagens, elastin, fibrillins, fibronectin, and laminins, and hydrophilic heteropolysaccharides, such as glycosaminoglycan chains in hyaluronan and proteoglycans. It is the combination of protein polymers and hydrated proteoglycans that gives extracellular matrices their resistance to tensile and compressive mechanical forces.

The macromolecular components of the polymeric assemblies of the ECM are in many cases secreted by cells as precursor molecules that are significantly modified (proteolytically processed, oxidized, and cross-linked) before they assemble with other components into functional polymers (Fig. 8.1). The formation of matrix assemblies *in vivo* is therefore in most instances a unidirectional, irreversible

process, and the disassembly of the matrix is not a simple reversal of assembly, but involves multiple, highly regulated processes. One consequence of this is that polymers reconstituted in the laboratory with components extracted from extracellular matrices do not have all the properties they have when assembled by cells *in vivo*. The ECM *in vivo* is also modified by cells as they proliferate, differentiate, and migrate, and cells in turn continuously interact with the matrix and communicate with each other through it (Hay, 1991).

The ECM is therefore not an inert product of secretory activities, but influences cellular shape, fate, and metabolism in ways that are as important to tissue and organ structure and function as the effects of many cytoplasmic processes. This realization has led to a reassessment of the need for a detailed molecular understanding of ECM. In the past, the ECM was appreciated primarily for its challenge to biochemists interested in protein and complex carbohydrate structure; a detailed characterization of ECM constituents is now considered essential for understanding cell behavior in the context of tissue and organ development and function. Some of these constituents are obviously most important for their structural properties (collagens and elastin), while others (fibronectin, fibrillin, laminin, thrombospondin, tenascin, perlecan, and other proteoglycans) are multidomain molecules that are both structural constituents as well as regulators of cell behavior (Fig. 8.1). In a third category are matrix-bound signaling molecules (matrix-bound FGFs, TGF- $\beta$ , and BMPs).

## II. COLLAGENS – MAJOR CONSTITUENTS OF ECM

### Fibrillar Collagens Are Major Tissue Scaffold Proteins

Collagens constitute a large family of proteins that represent the major proteins (about 25%) in mammalian tissues (Kielty and Grant, 2002). A subfamily of these proteins, the fibrillar collagens, contains rigid, rodlike molecules with three subunits,  $\alpha$ -chains, folded into a right-handed collagen triple helix. Within a fibrillar collagen triple helical domain, each  $\alpha$ -chain consists of about 1000 amino acid residues and is coiled into an extended, left-handed polyproline II helix; three  $\alpha$ -chains are in turn twisted into a right-handed superhelix (Fig. 8.2). The extended conformation of each  $\alpha$ -chain does not allow the formation of intrachain hydrogen bonds; the stability of the triple helix is instead due to interchain hydrogen bonds. Such interchain bonds can form only if every third residue of each  $\alpha$ -chain does not have a side chain and is packed close to the triple helical axis. Only glycine residues can therefore be accommodated in this position. This explains why the amino acid sequence of each  $\alpha$ -chain in fibrillar collagens consists of about 300 Gly-X-Y tripeptide repeats, where X and Y can be any residue but Y is frequently proline or hydroxyproline. It

**FIG. 8.1.** The life cycle of extracellular matrix molecules. Soluble matrix molecules are secreted by cells, modified by proteolysis, and assembled into polymeric complexes. These complexes serve as scaffolds for cells and as binding sites for small molecules, such as growth and differentiation factors. Depending on the growth factor and cellular context, this may either inhibit or stimulate growth factor activity. Degradation of the scaffolds, during normal tissue turnover or during wound healing, may release bound growth factors and/or release peptide fragments from the larger scaffold proteins; such fragments may bind to cellular receptors and regulate cellular behavior.

**FIG. 8.2.** Diagram showing a segment of a triple helical collagen molecule. The triple helix is composed of three left-handed helices ( $\alpha$ -chains) that are twisted into a right-handed superhelix. The sequence of each  $\alpha$ -chain is a repeat of the tripeptide Gly-X-Y. The Gly residues are packed close to the triple helical axis (indicated by a line through a triangle). Only glycine (without a side chain) can be accommodated in this position. Although any residue can fit into the X- and Y-positions, Pro is frequently found in the Y-position.

also provides an explanation for why mutations in collagens that lead to a replacement of triple helical glycine residues with more bulky residues can cause severe abnormalities.

Fibrillar collagen molecules are the major components of collagen fibrils. Their  $\alpha$ -chains are synthesized as precur-

**FIG. 8.3.** Diagram of a cartilage collagen fibril. Collagen II molecules are the major components. Molecules of collagens XI and IX are located on the surface. Collagen XI molecules, heterotrimers of three different  $\alpha$ -chains, have amino-terminal domains that are thought to sterically block the addition of collagen II molecules at the fibril surface.

sors, pro $\alpha$ -chains, with large propeptide regions flanking the central triple helical domain. The carboxyl propeptide (C-propeptide) is important for the assembly of trimeric molecules in the RER. Formation of C-propeptide trimers, stabilized by intra- and interchain disulfide bonds, is the first step in the intracellular assembly and folding of trimeric procollagen molecules (McAlinden *et al.*, 2003; Olsen, 1991). The folding of the triple helical domain at body temperature requires post translational hydroxylation of about 50% of the prolyl residues by prolyl hydroxylases and proceeds in a zipperlike fashion from the carboxyl toward the amino end of procollagen molecules. Mutations in fibrillar procollagens that affect the structure and folding of the C-propeptide domain are therefore likely to affect the participation of the mutated chains in triple helical assemblies. In contrast, mutations upstream of the C-propeptide, such as in-frame deletions or glycine substitutions in the triple helical domains, exert a dominant negative effect, in that the mutated chains will participate in trimer assembly but will interfere with subsequent folding of the triple helical domain.

Fibrillar procollagen chains are the products of 11 genes. The similarities between these genes suggest that they arose by multiple duplications from a single ancestral gene. Despite their similarities and the high degree of sequence identity between their protein products, they exhibit specificity in the interactions of their C-propeptides during intracellular trimeric assembly in the RER. Thus, a relatively small number of chain combinations are found among triple helical procollagens; these combinations represent fibrillar collagen types.

### Collagens V/XI – Regulators of Fibril Assembly, Spatial Organization, and Cell Differentiation

Some collagen types are heterotrimers (types I, V, and XI), while others are homotrimers (types II, III, XXIV, and XXVII). Some chains participate in more than one type: For example, the  $\alpha 1(\text{II})$  chain (encoded by the COL2A1 gene) forms the homotrimeric collagen II but is also one of three different chains in collagen XI molecules. Between collagens V and XI there is extensive sharing of polypeptide subunits, and fibrillar collagen molecules previously described as belonging to either collagen V or XI are now referred to as

belonging to the V/XI type. Thus, fibrillar procollagen molecules secreted by cells are members of a group of homologous proteins. They all contain a C-propeptide that is completely removed by an endoproteinase after secretion, and their triple helical rodlike domains polymerize in a staggered fashion into fibrillar arrays (Fig. 8.3). They differ, however, in the structure of their amino propeptide (N-propeptide) domains and in the extent to which this domain is proteolytically removed. For some collagen types, such as collagens I and II, the N-propeptide processing is complete in molecules within mature fibrils. For other types, such as collagens V/XI, this is not the case, in that a large portion of the N-propeptides in these molecules remain attached to the triple helical domain (Fig. 8.3). The incomplete processing of type V/XI molecules allows them to serve as regulators of fibril assembly (Linsenmayer *et al.*, 1993). Collagen fibrils are heterotypic, i.e., contain more than one collagen type, such that collagen I fibrils in skin, tendon, ligaments, and bone contain 5–10% collagen V, and collagen II fibrils in cartilage contain 5–10% collagen XI. The presence of N-propeptide domains on V/XI molecules represents a steric hindrance to addition of molecules at fibril surfaces. This heterotypic/steric hindrance model predicts that collagen fibril diameters in a tissue are determined by the ratio of the minor component (V/XI) to the major component (I or II). A high ratio results in thin fibrils; a low ratio results in thick fibrils. Direct support for this comes from studies of mutant and transgenic mice. For example, mice that are homozygous for a functional null mutation in  $\alpha 1(\text{XI})$  collagen and transgenic mice overexpressing collagen II have cartilage collagen fibrils that are abnormally thick (Garofalo *et al.*, 1993; Li *et al.*, 1995).

A characteristic feature of collagen fibrillar scaffolds is their precise three-dimensional patterns. These patterns follow mechanical stress lines and ensure a maximum of tensile strength with a minimum of material. Examples are the crisscrossing lamellae of collagen fibers in lamellar bone or in cornea, the arcades of collagen fibrils under the surface of articular cartilage, and the parallel-fiber bundles in tendons and ligaments. Ultimately, cells are responsible for establishing these patterns, but the cellular mechanisms involved are only beginning to be understood. A study by Canty *et al.* (2004) suggests that the orientation of collagen

fibrils in the extracellular space is linked to the cytoskeletal organization induced by cellular responses to mechanical stress. In tendon fibroblasts, Golgi-to-plasma transport carriers of collagen are formed on the exit side of the trans-Golgi network and move along cytoskeletal “tracks” into long cytoplasmic extensions. Collagen fibrils, forming inside the carriers, are oriented along the longitudinal axis of the carriers. When the membrane at the distal tip of the carrier fuses with the cell membrane covering the tip of the extension, the space within the carrier becomes continuous with the extracellular space and the fibrils are, in effect, moved from an intracellular to an extracellular compartment. Thus, the parallel orientation of collagen fibrils in a tendon is a consequence of the polarized structure, intracellular movement, and polarized exocytosis of fibril-containing Golgi-derived transport carriers. This cellular mechanism for orientation of collagen fibrils is consistent with data showing that the same kind of heterotypic fibril can be part of scaffolds with very different spatial organization. Transgenic mice with an alteration in the N-propeptide region of collagen V molecules show a disruption of the lamellar arrangement of fibrils in the cornea of the eye, suggesting a role for fibril surface domains in generating and/or stabilizing the spatial pattern (Andrikopoulos *et al.*, 1995). Finally, members of a unique subfamily of collagens, FACIT collagens (Olsen *et al.*, 1995), are good candidates for molecules that modulate the surface properties of fibrils and allow tissue-specific fibril patterns to be generated and stabilized by cells.

The phenotypic consequences of mutations in fibrillar collagen genes indicate that a major function of these proteins is to provide elements of high tensile strength at the tissue level. Thus, mutations in COL1A1 or COL1A2, the human genes encoding the  $\alpha 1$  and  $\alpha 2$  subunits of fibrillar collagen I (in bone, ligaments, tendons, and skin), cause osteogenesis imperfecta (brittle bone disease) or clinical forms of Ehlers–Danlos syndrome, characterized by skin hyperextensibility and fragility and joint hypermobility, with or without bone abnormalities (Byers and Cole, 2002; Steinmann *et al.*, 2002). Mutations in COL2A1, the gene encoding the  $\alpha$ -chains of collagen II (in cartilage), cause a spectrum of human disorders, ranging from lethal deficiency in cartilage formation to relatively mild deficiencies in cartilage mechanical properties and function (Horton and Hecht, 2002). Fibrillar collagens also have regulatory functions. For example, mutations in collagen V/XI genes suggest that fibrillar collagen scaffolds are essential for normal cellular growth and differentiation. A functional null mutation in  $\alpha 1$ (XI) collagen resulting in complete lack of collagen XI in cartilage causes a severe disproportionate dwarfism in mice and perinatal death of homozygotes (Li *et al.*, 1995). Histology of mutant long-bone growth plates reveals a disorganized spatial distribution of cells and a defect in chondrocyte differentiation to hypertrophy. The explanation for this is likely related to the fact that proliferation and

differentiation of chondrocytes in growth plates are regulated by locally produced growth factors and cytokines. Cells that produce these factors are localized close to cells that express the appropriate receptors. Lack of collagen XI may disrupt this relationship, since it results in a dramatic decrease in cohesive properties of the matrix and a loss of cellular organization. Transgenic mice with a mutation in  $\alpha 2$ (V) collagen have a large number of hair follicles of unusual localization in the hypodermis; this may be related to a defect in the mechanical properties of the fibrillar collagen scaffold but could also be mediated by an effect on extracellular signaling molecules (Andrikopoulos *et al.*, 1995).

### **FACIT Collagens – Modulators of Collagen Fibril Surface Properties**

Molecules that are associated with collagen fibrils, contain two or more triple helical domains, and share characteristic protein domains (modules) are classified as FACIT collagens (Olsen *et al.*, 1995; Shaw and Olsen, 1991). Of the eight known members in the group (collagens IX, XII, XIV, XVI, XIX, XX, XXI, and XXII), collagen IX is the best characterized both structurally and functionally. Collagen IX molecules are heterotrimers of three different gene products (van der Rest *et al.*, 1985). Each of the three  $\alpha$ -chains contains three triple helical domains separated and flanked by non-triple helical sequence regions (Fig. 8.4). Between the amino-terminal and central triple helical domains, a flexible hinge gives the molecule a kinked structure with two arms. Type IX molecules are located on the surface of type II/XI containing fibrils with the long arm parallel to the fibril surface and the short arm projecting into the perifibrillar space (Vaughan *et al.*, 1988) (Fig. 8.3). Collagen IX functions as a bridging molecule between fibrils, between fibrils and other matrix constituents (Pihlajamaa *et al.*, 2004), and between fibrils and cells (Kapyla *et al.*, 2004). Transgenic mice with a dominant-negative mutation in the  $\alpha 1$ (IX)-chain (Nakata *et al.*, 1993), as well as mice that are homozygous for null alleles of the gene (Col9a1) coding for  $\alpha 1$ (IX) (Faessler *et al.*, 1994), exhibit osteoarthritis in knee joints and mild chondrodysplasia. In humans, mutations in the  $\alpha 1$ (IX),  $\alpha 2$ (IX), or  $\alpha 3$ (IX) collagen chains cause a form of multiple epiphyseal dysplasia, an autosomal dominant disorder characterized by early-onset osteoarthritis in large joints associated with short stature and stubby fingers (Jakkula *et al.*, 2005; Muragaki *et al.*, 1996).

Molecules of collagens XII and XIV are homotrimers of chains that are made up of several kinds of modules. Some modules are homologous to modules found in collagen IX, while others show homology to von Willebrand factor A domains and fibronectin type 3 repeats. Both types of molecules contain a central globule with three fingerlike extensions and a thin triple helical tail attached (Fig. 8.4). For collagen XII, two forms that differ greatly in the lengths of

**FIG. 8.4.** Diagrams of collagen IX and XII (long-form) molecules. Collagen IX molecules contain the three chains  $\alpha 1(\text{IX})$ ,  $\alpha 2(\text{IX})$ , and  $\alpha 3(\text{IX})$ . Each chain contains three triple helical domains (COL1, COL2, COL3), interrupted and flanked by non-triple helical sequences. In cartilage, the  $\alpha 1(\text{IX})$ -chain contains a large globular amino-terminal domain. The  $\alpha 2(\text{IX})$ -chain serves as a proteoglycan core protein, in that it contains a chondroitin sulfate (CS-) side chain attached to the non-triple helical region between the COL2 and COL3 domains. Collagen XII molecules are homotrimers of  $\alpha 1(\text{XII})$ -chains. The three chains form two short triple helical domains separated by a flexible hinge region. A central globule is composed of three globular domains that are homologous to the amino-terminal globular domain of  $\alpha 1(\text{IX})$  collagen chains. The amino-terminal region of the three  $\alpha 1(\text{XII})$ -chains contain multiple fibronectin type 3 repeats and von Willebrand factor A-like domains. These regions form three “fingers” that extend from the central globule. Through alternative splicing a portion of the “fingers” (white region in the diagram) is spliced out in the short form of collagen XII. Hybrid molecules with both long and short “fingers” can be extracted from tissues.

the fingerlike extensions are generated by alternative splicing of RNA transcripts. Variations in the carboxyl regions also occur (Olsen *et al.*, 1995). Both collagens XII and XIV are found in connective tissues containing type I collagen fibrils, except mineralized bone matrix, and immunolabeling studies show a fibril-associated distribution. Type XIV collagen can bind to heparin sulfate and the small fibril-associated proteoglycan decorin (Brown *et al.*, 1993; Font *et al.*, 1993). This would suggest an indirect fibril association. A direct association is also possible, since collagen XII molecules form copolymers with collagen I even in the absence of proteoglycans. A functional interaction between fibrils and collagens XII and XIV is implied by studies showing that addition of the two collagens to type I collagen gels promote gel contraction mediated by fibroblasts

(Nishiyama *et al.*, 1994). The effect is dose dependent and can be prevented by denaturation or addition of specific antisera. The association of collagens XII and XIV with fibrils may therefore modulate the frictional properties of fibril surfaces. The synthesis of different isoforms could be important in this context, since they could bind to fibrils with different affinities. Also, since the long form of collagen XII is a proteoglycan, whereas the short form is not, variations in the relative proportion of the two splice variants may serve to modulate the hydrophilic properties of interfibrillar matrix compartments. Finally, the discovery that the collagen I N-propeptide-processing enzyme (see later) binds to collagen XIV and can be purified as part of a complex with antibodies against collagen XIV suggests that the FACIT collagens provide binding sites for fibril-modifying extracellular matrix enzymes (Colige *et al.*, 1995).

### Basement Membrane Collagens and Associated Collagen Molecules

At epithelial (and endothelial)–stromal boundaries, basement membranes serve as specialized areas of ECM for cell attachment. Collagen IV molecules form a networklike scaffold in basement membranes by end-to-end and lateral interactions (Yurchenco *et al.*, 2004). Six different collagen IV genes exist in mammals, and their products interact to form at least three different types of heterotrimeric collagen IV molecules. These different isoforms show characteristic tissue-specific expression patterns. The physiological importance of collagen IV isoforms is highlighted by Alport syndrome (Tryggvason and Martin, 2002). This disease, characterized by progressive hereditary nephritis associated with sensorineural hearing loss and ocular lesions, can be caused by mutations within  $\alpha 3(\text{IV})$  and  $\alpha 4(\text{IV})$  collagen genes (autosomal Alport syndrome) or mutations in  $\alpha 5(\text{IV})$  collagen (X-linked Alport syndrome). In cases of large deletions including both the  $\alpha 5(\text{IV})$  and the neighboring  $\alpha 6(\text{IV})$  collagen genes, renal disease is associated with inherited smooth muscle tumors.

Within basement membranes, the collagen IV networks are associated with a large number of noncollagenous molecules, such as various isoforms of laminin, nidogen, and the heparin sulfate proteoglycan perlecan (Fig. 8.5). Additional collagens are also associated with basement membranes. These include the transmembrane collagen XVII in hemidesmosomes and collagen VII in anchoring fibrils. Collagens XVII and VII are important in regions of significant mechanical stress, such as skin, in that they anchor epithelial cells to the basement membrane (collagen XVII) and strap the basement membrane to the underlying stroma (collagen VII) (Fig. 8.6). In bullous pemphigoid, autoantibodies against collagen XVII cause blisters that separate epidermis from the basement membrane; dominant and recessive forms of epidermolysis bullosa can be caused by mutations in collagens VII and XVII (Franzke *et al.*, 2003; Uitto and Richard, 2005).

**FIG. 8.5.** Components of basement membranes. Basement membranes contain interconnected networks of collagen IV and laminin polymers, together with nidogen, perlecan, and collagen XVIII. Collagen XVIII molecules are located at the boundary between the lamina densa and the sublamina matrix, with their carboxyl endostatin domain within the lamina densa and the amino end projecting into the underlying matrix.

**FIG. 8.6.** Epidermal basement membrane and associated collagens and laminins. Basal portion of a keratinocyte with hemidesmosome, anchoring filaments of collagen XVII and anchoring fibril of collagen VII. A complex of laminin-332, laminin-311, and integrin  $\alpha 6 \beta 4$  provides further strength to the cell-basement membrane junction.

Two additional basement membrane-associated collagens, collagen VIII and collagen XVIII, are of interest because of their function in vascular physiology and pathology. Collagen VIII is a short-chain, nonfibrillar collagen with significant homology to collagen X, a product of hypertrophic chondrocytes in long-bone growth plates and cartilage growth regions (synchondroses) at the skull base. Collagen VIII expression is up-regulated during heart development (Iruela-Arispe and Sage, 1991), in human atherosclerotic lesions (MacBeath *et al.*, 1996), and following experimental damage to the endothelium in large arteries (Bendeck *et al.*, 1996). Collagen VIII may be important in facilitating the

migration of smooth muscle cells from the medial layer into the intima during neointimal thickening following endothelial cell injury. Collagen VIII molecules are also major building blocks of Descemet's membrane, the thick basement membrane that bridges the corneal stroma with the corneal endothelium on the inside of the cornea (Hopfer *et al.*, 2005). Mutations in collagen VIII can cause clouding of the cornea and blurred vision (corneal dystrophy) in humans (Biswas *et al.*, 2001).

Collagen XVIII, together with collagen XV, belongs to a distinct subfamily of collagens called *multiplexins* because of their multiple triple-helix domains and interruptions (Oh *et al.*, 1994; Rehn and Pihlajaniemi, 1994). Because of the alternative utilization of two promoters and alternative splicing, the COL18A1 gene gives rise to three different transcripts that are translated into three protein variants. These are localized in various basement membranes (Fig. 8.5), including those that separate vascular endothelial cells from the underlying intima in blood vessels (Marneros and Olsen, 2001). Collagen XVIII  $\alpha$ -chains contain several consensus sequences for attachment of heparan sulfate side chains, and studies have, in fact, confirmed that collagen XVIII forms the core protein of a basement membrane proteoglycan (Halfter *et al.*, 1998). Proteolytic processing of the carboxyl non-triple helical domain of collagen XVIII in tissues leads to the release of a heparin binding fragment with anti-angiogenic activity.

This fragment, named *endostatin*, represents the carboxyl-terminal 20-kDa portion of collagen XVIII chains (Fig. 8.5) (O'Reilly *et al.*, 1997). Endostatin has been shown to inhibit the proliferation and migration of vascular endothelial cells, inhibit the growth of tumors in mice and rats, and cause regression of tumors in mice (Marneros and Olsen, 2001). The antitumor effects are mediated by inhibition of tumor-induced angiogenesis. The x-ray crystallographic structure of mouse and human endostatin proteins (Ding *et al.*, 1998; Hohenester *et al.*, 1998) shows a compact structure consisting of two  $\alpha$ -helices and a number of  $\beta$ -strands, stabilized by two intramolecular disulfide bonds. A coordinated zinc atom is part of the structure, and on the surface a patch of basic residues forms a binding site for heparin. Studies of mutant endostatins have shown that specific arginines within this patch are required for heparin binding (Yamaguchi *et al.*, 1999).

The physiological function of collagen XVIII is highlighted by the consequences of loss-of-function mutations in this basement membrane component (Marneros and Olsen, 2005). In humans, collagen XVIII mutations cause Knobloch syndrome, a recessive eye disorder in which affected individuals lose their eyesight at an early age because of degeneration of the retina and the vitreous. Mice with inactivated collagen XVIII genes exhibit age-dependent changes in the retina and the pigment epithelial layer behind the retina. These changes are similar to what is seen in age-dependent macular degeneration in humans

and lead (as in humans) to gradual loss of eyesight (Marneros and Olsen, 2005).

Of considerable interest is the finding that proteolytic fragments of basement membrane components other than collagen XVIII also have antiangiogenic properties (Bix and Iozzo, 2005). Molecules that give rise to such fragments include collagen IV and perlecan, the major heparan sulfate proteoglycan in basement membranes. The fragments involved show no sequence homology with endostatin, so it is likely that the molecular mechanisms underlying the antiangiogenic effects are different. For example, endostatin is a heparin-binding molecule, and its ability to inhibit angiogenesis is in many contexts heparan sulfate dependent. In contrast, the fragment from perlecan, called *endorepellin*, does not bind to heparin, and its inhibitory effects on vascular endothelial cells is heparan sulfate independent. In any case, release of such fragments as vascular basement membranes are degraded at sites of sprouting angiogenesis are likely to provide a local mechanism of negative control to balance the effects of proangiogenic factors.

### III. ELASTIC FIBERS AND MICROFIBRILS

Collagen molecules and fibers evolved as structures of high tensile strength, equivalent to that of steel when compared on the basis of the same cross-sectional area but three times lighter on a per-unit weight basis. In contrast, elastic fibers, composed of molecules of elastin, provide tissues with elasticity so that they can recoil after transient stretch (Rosenbloom *et al.*, 1993; von der Mark and Sorokin, 2002). In organs such as the large arteries, skin, and lungs, elasticity is obviously crucial for normal functioning. Elastin fibers derive their impressive elastic properties, an extensibility that is about five times that of a rubber band with the same cross-sectional area, from the structure of elastin molecules. Each molecule is composed of alternating segments of hydrophobic and  $\alpha$ -helical Ala- and Lys-rich sequences. Oxidation of the lysine side chains by the enzyme lysyl oxidase leads to formation of reactive aldehydes and extensive covalent cross-links between neighboring molecules in the fiber. It is thought that the elasticity of the fiber is due to the tendency of the hydrophobic segments to adopt a random-coil configuration following stretch.

On the surface of elastic fibers one finds a cover of microfibrils, beaded filaments with molecules of fibrillin as their major components (Corson *et al.*, 2004; Sakai and Keene, 1994). The fibrillins, products of genes on chromosomes 5 (FIB5), 15 (FIB15), and 19 (FIB19) in humans, also form microfibrils that are found in almost all extracellular matrices in the absence of elastin. Fibrillin molecules are composed of multiple repeat domains, the most prominent being calcium-binding EGF-like repeats; similar repeats in latent TGF- $\beta$ -binding proteins suggest that the fibrillins belong to a superfamily of proteins. The physiological

importance of fibrillin is highlighted by mutations causing the Marfan syndrome and congenital contractural arachnodactyly in humans (Pyeritz and Dietz, 2002). The Marfan syndrome is caused by mutations in FIB15 and is characterized by dislocation of the eye lens due to weakening of the suspensory ligaments of the zonule, congestive heart failure, aortic aneurysms, and skeletal growth abnormalities resulting in a tall frame, scoliosis, chest deformities, arachnodactyly, and hypermobile joints. In patients with congenital contractural arachnodactyly, mutations in FIB5 lead to similar skeletal abnormalities and severe contractures but no ophthalmic and cardiovascular manifestations. The tall stature and arachnodactyly seen in patients with the Marfan syndrome suggest that FIB15 is a negative regulator of longitudinal bone growth. Since fibrillin microfibrils are found in growth plate cartilage, it is conceivable that they affect chondrocyte proliferation and/or maturation.

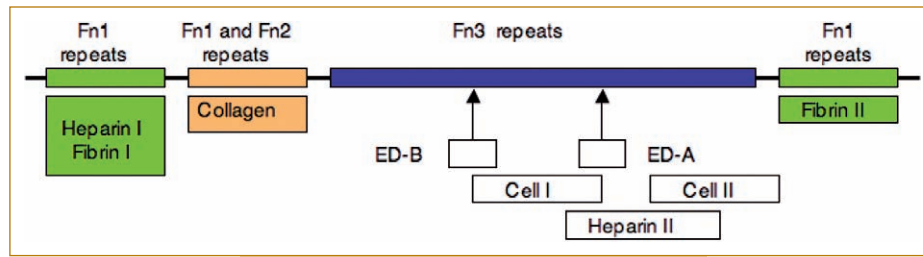

A regulatory role for fibrillin in growth plates would be consistent with the function of fibrillin in other tissues (Isogai *et al.*, 2003). In lung tissue and blood vessel walls, fibrillin functions as a regulator of TGF- $\beta$  activity. Fibrillin mutations in mouse models of Marfan syndrome are associated with increased TGF- $\beta$  activity in lungs and the aorta, causing impaired alveolar septation in lungs and widening and weakening (aneurysms) of the aorta. Inhibition of TGF- $\beta$  largely prevents these defects (Habashi *et al.*, 2006; Neptune *et al.*, 2003). Some of the major clinical abnormalities in patients with Marfan syndrome are therefore likely a consequence of altered fibrillin-mediated control of TGF- $\beta$  activity and not loss of fibrillin as a structural molecule. The current data suggest that drugs to inhibit TGF- $\beta$  activity may prevent early death caused by aortic aneurysms in Marfan syndrome patients. Clinical trials are under way to test this hypothesis. If successful, this would represent an exciting example of how a genetic disease may be effectively treated by pharmacological modulation of pathogenetic consequences of the mutation, without correcting the mutation.

### IV. OTHER MULTIFUNCTIONAL PROTEINS IN ECM

Several proteins in the extracellular matrix contain binding sites for structural macromolecules and for cells, thus contributing to both the structural organization of ECM and its interaction with cells (von der Mark and Sorokin, 2002). The prototype of these adhesive proteins is fibronectin.

#### Fibronectin Is a Multidomain, Multifunctional Adhesive Glycoprotein

Fibronectin is a disulfide-bonded dimer of 220- to 250-kDa subunits (Hynes, 1990). Each subunit is folded into rodlike domains separated by flexible "joints." The domains are composed of three types of multiple repeats or modules, Fn1, Fn2, and Fn3. Fn1 modules are found in the fibrin-

**FIG. 8.7.** Diagram of a fibronectin polypeptide chain. The polypeptide chain is composed of several repeats (Fn1, Fn2, and Fn3) and contains binding sites for several matrix molecules and cells. Two regions can bind heparin and fibrin, and two regions are involved in cell binding as well. By alternative splicing, isoforms are generated that may or may not contain certain Fn3 domains (labeled ED-A and ED-B in the diagram). Additional splice variations in the second cell-binding domain (Cell II) generate other isoforms.

binding amino- and carboxyl-terminal regions of fibronectin and in a collagen (gelatin)-binding region (Fig. 8.7). Single copies of Fn1 modules are also found in other proteins, such as tissue-type plasminogen activator (t-PA) and coagulation factor XII (Potts and Campbell, 1994).

NMR studies of Fn1 modules demonstrate the presence of two layers of antiparallel  $\beta$ -sheets (two strands in one layer and three strands in the other) held together by hydrophobic interactions. The structure is further stabilized by disulfide and salt bridges. Fn2 modules are found together with Fn1 modules in the collagen-binding region of fibronectin and in many other proteins. Their structure, two double-stranded antiparallel  $\beta$ -sheets connected by loops, suggests that a ligand such as collagen may bind to this module through interactions of hydrophobic amino acid side chains with its hydrophobic surface. Fn3 modules are the major structural units in fibronectin and are found in a large number of other proteins as well. Some of these proteins (for example, the long-splice variant of collagen XII) contain more Fn3 modules than fibronectin itself. The structure of Fn3 is that of a sandwich of antiparallel  $\beta$ -sheets (three strands in one layer and four strands in the other) with a hydrophobic core. The binding of fibronectin to some integrins involves the tripeptide sequence Arg-Gly-Asp in the 10th Fn3 module; these residues lie in an exposed loop between two of the strands in one of the  $\beta$ -sheets (Potts and Campbell, 1994).

Fibronectin can assemble into a fibrous network in the ECM through interactions involving cell surface receptors and the amino-terminal region of fibronectin (Mosher *et al.*, 1991). A fibrin-binding site is also contained in this region; a second site is in the carboxyl domain. The ability to bind to collagen ensures association between the fibronectin network and the scaffold of collagen fibrils. Binding sites for heparin and chondroitin sulfate further make fibronectin an important bridging molecule between collagens and other matrix molecules (Fig. 8.7).

Transcripts of the fibronectin gene are alternatively spliced in a cell- and developmental stage-dependent manner. As a result there are many different isoforms of fibronectin (Schwarzbauer, 1990). The main form produced

by the liver and circulating in plasma lacks two of the Fn3 repeats found in cell- and matrix-associated fibronectin. One alternatively spliced domain is adjacent to the heparin-binding site, and this region binds to integrins  $\alpha 4\beta 1$  and  $\alpha 4\beta 7$ . Thus, there is a mechanism for fine-tuning of fibronectin structure and interaction properties. Not surprisingly, mice that are homozygous for fibronectin null alleles die early in embryogenesis with multiple defects (George *et al.*, 1993).

The biologically most important activity of fibronectin is its interaction with cells. The ability of fibronectin to serve as a substrate for cell adhesion, spreading, and migration is based on the activities of several modules. The Arg-Gly-Asp sequence in the 10th Fn3 module plays a key role in the interaction with the integrin receptor  $\alpha 5\beta 1$ , but synergistic interactions with other Fn3 modules are essential for high-affinity binding of cells to fibronectin (Aota *et al.*, 1991).

### Laminins Are Major Components of Basement Membranes

Laminins are trimeric basement membrane molecules of  $\alpha$ -,  $\beta$ -, and  $\gamma$ -chains (Timpl and Brown, 1994; Yurchenco *et al.*, 2004). With a large number of genetically distinct chains, more than 15 different trimeric isoforms are known from mice and humans. A recently proposed nomenclature introduced a systematic approach to naming the different trimers; they are now named on the basis of their chain composition (i.e.,  $\alpha 1\beta 1\gamma 1$ ) or by numbers, only without the greek letters (i.e., 111 instead of  $\alpha 1\beta 1\gamma 1$ ) (Aumailley *et al.*, 2005). Several forms have a cross-shaped structure as visualized by rotary shadowing electron microscopy; some forms contain T-shaped molecules (Fig. 8.8).

In basement membranes, laminins provide interaction sites for many other constituents, including cell surface receptors (Timpl, 1996). The functional and structural mapping of these sites and the complete sequencing of many laminin chains has provided detailed insights into the organization of laminin molecules. Within the cross-shaped laminin-111 molecule, three similar short arms are formed by the N-terminal regions of the  $\alpha 1$ -,  $\beta 1$ -, and  $\gamma 1$ -chains, whereas a long arm is composed of the carboxyl regions of

**FIG. 8.8.** Diagrams of two types of laminins. Laminin-111 has a cross-shaped structure; laminin-332 is T-shaped, due to a shorter  $\alpha$ -chain.

all three chains (Fig. 8.8). The three chains are connected at the center of the cross by interchain disulfide bridges. The short arms contain multiple EGF-like repeats of about 60 amino acid residues, terminated and interrupted by globular domains. The long arm consists of heptad repeats covering about 600 residues in all three chains folded into a coiled-coil structure. The  $\alpha$ 1-chain is about 1000 amino acid residues longer than the  $\beta$ 1- and  $\gamma$ 1-chains and forms five homologous globular repeats at the base of the cross; these globular repeats are similar to repeats found in the proteoglycan molecule perlecan, also a component of basement membranes (Fig. 8.5) (Olsen, 1999).

Calcium-dependent polymerization of laminin is based on interactions between the globular domains at the N-termini and is thought to be important for the assembly and organization of basement membranes. Of significance for the assembly of basement membranes is also the high-affinity interaction with nidogen (Yurchenco *et al.*, 2004). The binding site in laminin for nidogen is on the  $\gamma$ 1-chain, close to the center of the cross (Fig. 8.5). On nidogen, a rodlike molecule with three globular domains, the binding site for laminin is in the carboxyl globular domain, while another globular domain binds to collagen IV. Thus, nidogen is a bridging molecule that connects the laminin and collagen IV networks and is important for the assembly of normal basement membranes.

Laminin does not bind directly to collagen IV, but has binding sites for several other molecules besides nidogen. These are heparin, perlecan, and fibulin-1, which bind to the end of the long arm of the laminin cross. However, the biologically most significant interactions of laminin involve a variety of both integrin and nonintegrin cell surface receptors. Several integrins are laminin receptors. They show distinct preferences for different laminins and recognize

binding sites on either the short or long arms of laminin molecules.

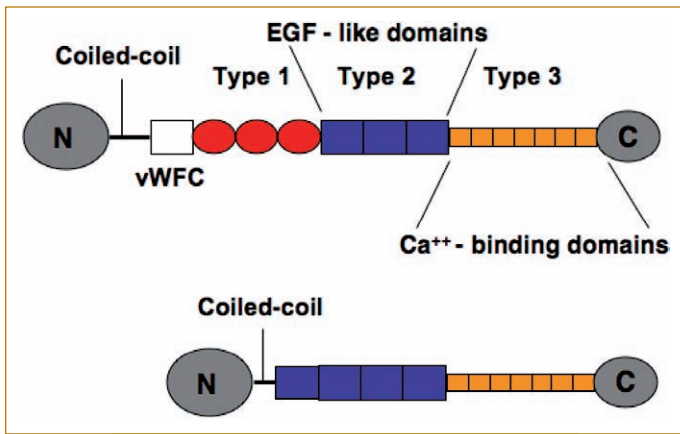

The different laminin genes likely arose through duplication of a single ancestral gene (Miner and Yurchenco, 2004). The laminins most closely related to this ancestral gene, laminin-111 and laminin-511, are crucial for early steps in development, including gastrulation, placentation, and neural tube closure. In contrast, laminins that have evolved more recently are adapted to more specialized functions in the development and function of specific organs. For example, laminin  $\alpha$ 2 $\beta$ 1 $\gamma$ 1 is a major laminin in the basement membranes surrounding skeletal muscle fibers, where it provides binding sites for the dystroglycan–dystrophin complex, linking the muscle cell cytoskeleton to the basement membrane. In skin, a disulfide-linked complex of laminins  $\alpha$ 3 $\beta$ 3 $\gamma$ 2 and  $\alpha$ 3 $\beta$ 1 $\gamma$ 1 is crucial for the firm attachment of keratinocytes to the basement membrane by its interaction with  $\alpha$ 6 $\beta$ 4 integrins in hemidesmosomes (Fig. 8.6). Mutations in any one of three genes encoding the subunits of laminin-332 cause autosomal recessive junctional epidermolysis bullosa, a lethal skin-blistering disorder in which the epidermal cell layers are separated from the underlying epidermal basement membrane. Loss-of-function mutations in the laminin  $\alpha$ 2 gene cause congenital muscular dystrophy both in mice and in humans.

Mice with targeted disruption of the laminin  $\alpha$ 3 gene develop a blistering skin disease similar to the disorder in human patients. In addition, the kidneys of the mutant animals show arrested development of glomeruli, with a failure to develop glomerular capillaries with fenestrated endothelial cells and lack of migration of mesangial cells into the glomeruli (Abrass *et al.*, 2006). In humans, mutations resulting in laminin  $\beta$ 2 deficiency cause a syndrome of loss of albumin and other plasma proteins through the glomerular basement membrane (congenital nephrotic syndrome), combined with sclerosis of the glomerular mesangium and severe impairment of vision and neurodevelopment (Zenker *et al.*, 2004).

### Other Modulators of Cell–Matrix Interactions

Whereas proteins such as fibronectin and laminin are important for adhesion of cells to extracellular matrices, other ECM molecules function as both positive and negative modulators of such adhesive interactions. Examples of such modulators are thrombospondin (Adams and Lawler, 2004) and tenascin (Chiquet-Ehrismann, 2004). Thrombospondins (TSPs) are a group of homologous trimeric (TSP-1 and TSP-2) and pentameric (TSP-3, TSP-4 and TSP-5/COMP) matrix proteins composed of several  $\text{Ca}^{++}$ -binding (type 3) domains, EGF-like repeats (type 2), as well as other modules (Fig. 8.9). Different members of the group show differences in cellular expression and functional properties. The most highly conserved regions of the different thrombospondins are the carboxyl halves of the molecules, all consisting of a variable number of EGF-like domains, seven  $\text{Ca}^{++}$ -binding

**FIG. 8.9.** Diagram of thrombospondins. Diagram of trimeric thrombospondins (TSP-1 and TSP-2) on top showing the multidomain structure and the location of the coiled-coil domain important for trimerization. Diagram of pentameric thrombospondins (TSP-3, TSP-4, and TSP-5/COMP) at bottom, showing the lack of von Willebrand factor C-like domain (vWFC) and type 1 repeats in this group of thrombospondins.

TSP type 3 repeats, and a C-terminal globular domain. In contrast, the N-terminal regions are quite variable, but all members have a short coiled-coil domain of heptad repeats in this region that is crucial for oligomerization into trimers in TSP-1 and TSP-2 or pentamers in TSP-3, TSP-4, and TSP-5/COMP. These oligomerization domains are stabilized by interchain disulfide bonds, but they are quite stable even with the disulfides reduced (Engel, 2004). Since the subunits are held together at the coiled-coil domains, the assembled molecules have a flowerlike appearance, with three or five “petals” extending out from the center, available for binding to cell surface receptors and other ECM molecules. The crystal structure of the five-stranded coiled-coil domain of TSP-5 shows that it forms a hydrophobic channel with some similarity to ion channels and can bind vitamin D and all-trans retinoic acid. One function of pentameric thrombospondins may therefore be to store small hydrophobic signaling molecules in the ECM.

Interestingly, TSP type 1 repeats are found in many other proteins, including the large family of matrix metalloproteases called ADAMTS enzymes; in some members of this family, there are more copies of TSP type 1 domains than in TSP-1 or TSP-2 themselves (Tucker, 2004). Members of the ADAMTS family have important biological functions (Apte, 2004). For example, ADAMTS2, ADAMTS3, and ADAMTS14 are procollagen propeptidases, responsible for processing the amino propeptide in fibrillar procollagens (see earlier), and ADAMTS4 and ADAMTS5 are aggrecanases, able to degrade the major proteoglycan component of cartilage.

The carboxyl regions of thrombospondins can bind to a variety of ECM molecules, extracellular proteases, and cell surface components such as integrins (Adams, 2004).

Their oligomeric structure enables thrombospondins to be involved in multiple interactions and to modulate both cellular behavior and ECM assembly. All thrombospondins support attachment of cells in a  $\text{Ca}^{++}$ -dependent manner and stimulate cell migration, proliferation, chemotaxis, and phagocytosis. Trimeric thrombospondins (TSP-1 and TSP-2) have additional activities associated with the type 1 domains within their N-terminal regions (Bornstein *et al.*, 2004). These activities include inhibition of angiogenesis through mechanisms by which thrombospondin induces endothelial cell apoptosis and inhibits mobilization of vascular endothelial growth factor (VEGF). The two trimeric thrombospondins have also recently been shown to promote the formation of synapses in the central nervous system (Christopherson *et al.*, 2005).

Cartilage oligomeric matrix protein (TSP-5/COMP) is thought to have evolved from the TSP-3 and TSP-4 branches of the thrombospondin (Posey *et al.*, 2004). COMP is a secretory product of chondrocytes and is localized in their territorial matrix in cartilage. Beyond the fact that COMP interacts with collagens II and IX, little is known about its normal function in cartilage. Mice lacking COMP develop a normal skeleton and have no significant abnormalities. However, mutations in COMP cause pseudoachondroplasia and multiple epiphyseal dysplasia in humans (Briggs *et al.*, 1995; Horton and Hecht, 2002). At birth, affected individuals have normal weight and length but show reduced growth of long limb bones and striking defects in growth plate regions. These defects are caused by retention of mutant protein in the RER of chondrocytes, causing premature cell death. Mutations in COMP appear therefore to generate a mutant phenotype by a mechanism involving RER stress in chondrocytes.

The four members of the vertebrate tenascin family (C, R, W, and X) are large multimeric proteins with subunits composed of multiple protein modules (Chiquet-Ehrismann, 2004). The modules include heptad repeats, fibronectin type 3 repeats, EGF-like domains, and a carboxyl domain with homology to the carboxyl-terminal domains of  $\beta$ - and  $\gamma$ -fibrinogen chains. These modules form rodlike structures that interact with their amino-terminal domains to form oligomers. Alternative splicing of tenascin-C generates multiple isoforms. The tenascins are differentially expressed in different tissues and at different times during development and growth (Chiquet-Ehrismann and Tucker, 2004). For example, tenascin-R is expressed only in the central nervous system, in contrast to tenascin-C, which is found in both the central nervous system as well as peripheral nerves. Tenascin-C expression is high during development and inflammation and around tumors, but it is otherwise relatively low in postnatal tissues, with some interesting exceptions. In tissue regions of high mechanical stress, the levels of tenascin expression are high, suggesting a role for tenascin-C in the mechanisms used by cells to cope with mechanical stress. In fact, tenascin-C was first

identified as a myotendinous antigen because of the high level of expression at tendon–muscle junctions (Chiquet and Fambrough, 1984). It is also expressed by other cells that are exposed to mechanical stress, including osteoblasts, perichondrial cells around cartilage, smooth muscle cells, and fibroblasts in healing wounds. This association between mechanical stress and expression is also seen for other tenascins. Thus, tenascin-W is expressed by both osteoblasts and smooth muscle cells, and tenascin-X is expressed at high level in the connective tissue “wraps” in skeletal muscle. Consistent with a mechanical role in connective tissues is also the finding that a form of Ehlers–Danlos syndrome, with hypermobile joints and hyperelastic skin, is caused by a deficiency in tenascin-X (Schalkwijk *et al.*, 2001).

The finding that collagen XII (see earlier) interacts with tenascin-X, combined with data showing that tenascin-X can bind to collagen I fibrils, possibly via interaction with the small proteoglycans decorin, suggests that a complex of collagen XII and tenascin-X serves as important interfibrillar bridges in skin (Veit *et al.*, 2006). This complex may also mediate attachment of collagen fibrils to cells, since tenascin can bind to integrin receptors. That a similar complex between collagen XII and tenascin-C may be present at myotendinous junctions is suggested by the high-level expression of both collagen XII and tenascin-C at such junctions (Böhme *et al.*, 1995).

The interactions between tenascins and cells are relatively weak compared to other proteins, such as fibronectin and thrombospondin. In certain experimental conditions, tenascin-C can be an adhesive molecule for cells; it can also, however, have antiadhesive effects (Chiquet-Ehrismann and Tucker, 2004; Orend and Chiquet-Ehrismann, 2006). The adhesive activity can be mediated by either cell surface proteoglycans or integrins, depending on cell type. Tenascin-C can bind heparin, and this may be responsible for interactions with cell surface proteoglycans such as glypican. Tenascin-C can also block adhesion by covering up adhesive sites in other matrix molecules, such as fibronectin, and sterically block their interactions with cells. Tenascin-C has therefore been characterized as a cell adhesion–modulating protein. Likewise, tenascin-R can both promote neuronal cell adhesion and act as a repellent for neurites.

## V. PROTEOGLYCANS – MULTIFUNCTIONAL MOLECULES IN THE EXTRACELLULAR MATRIX AND ON CELL SURFACES

A variety of proteoglycans play important roles in cellular growth and differentiation and in matrix structure. They range from the large hydrophilic space-filling complexes of aggrecan and versican with hyaluronan, to the cell

surface syndecan receptors. In basement membranes the major heparan sulfate proteoglycan is perlecan (Timpl, 1994). With three heparan sulfate side chains attached to the amino-terminal region, its core protein is multimodular in structure, having borrowed structural motifs from a variety of other genes. These include an LDL receptor-like module, regions with extensive homology to laminin chains, a long stretch of N-CAM-like IgG repeats, and a carboxyl-terminal region with three globular and four EGF-like repeats similar to a region of laminin (Olsen, 1999). Alternative splicing can generate molecules of different lengths. Perlecan is present in a number of basement membranes, but it is also found in the pericellular matrix of fibroblasts and in cartilage ECM. In fact, fibroblasts, rather than epithelial cells, appear to be major producers of perlecan (for example, in skin). In liver, perlecan is expressed by sinusoidal endothelial cells and is localized in the perisinusoidal space. Mutations in the *unc-52* gene in *C. elegans*, encoding a short version of perlecan, cause disruptions of skeletal muscle (Rogalski *et al.*, 1993). This indicates that the molecule, as a component of skeletal muscle basement membranes, is important for assembly of myofilaments and their attachment to cell membranes. Binding of growth factors and cytokines to the heparan sulfate side chains also enables perlecan to serve as a storage vehicle for biologically active molecules such as bFGF. The critical role of perlecan is further highlighted by the dramatic effects of knocking out the perlecan gene in mice (Costell *et al.*, 1999). Most of the mutant embryos die halfway through pregnancy, and the few embryos that survive to birth have severe defects in the brain and the skeleton. The skeletal defects include severe shortening of axial and limb bones and disruption of normal growth plate structure.

Several small leucine-rich repeat proteins and proteoglycans with homologous core proteins are found in a variety of tissues, where they interact with other matrix macromolecules and regulate their functions (McEwan *et al.*, 2006). They include decorin, biglycan, lumican, and fibromodulin. Decorin binds along collagen fibrils and plays a role in regulating fibril assembly and mechanical properties (Reed and Iozzo, 2002; Robinson *et al.*, 2005). It also modulates the binding of cells to matrix constituents such as collagen, fibronectin, and tenascin (Ameys and Young, 2002). Through binding of TGF- $\beta$  isoforms, the small proteoglycans help sequester growth factors within the ECM and thus regulate their activities (Hildebrand *et al.*, 1994).

A variety of proteoglycans also have important functions at cell surfaces. These include members of the syndecan family, transmembrane molecules with highly conserved cytoplasmic domains, and glypican-related molecules that are linked to the cell surface via glycosyl phosphatidylinositol. Through their heparan sulfate side chains these molecules can bind growth factors, protease inhibitors, enzymes, and matrix macromolecules. They are therefore important modulators of cell signaling pathways and cell–matrix

**FIG. 8.10.** Diagram of a portion of a large proteoglycan complex from cartilage. Monomers of aggrecan, composed of core proteins with glycosaminoglycan side chains (mostly chondroitin sulfate), are bound to hyaluronan. The binding is stabilized by link proteins. For clarity, only some of the glycosaminoglycan side chains are shown in the monomers.

contacts (De Cat and David, 2001; Tkachenko *et al.*, 2005; Zimmermann and David, 1999).

Hyaluronan is an important component of most extracellular matrices (Laurent and Fraser, 1992). It serves as a ligand for several proteins, including cartilage link protein and aggrecan and versican core proteins. In cartilage, based on such interactions, it is the backbone for the large proteoglycan complexes responsible for the compressive properties of cartilage (Morgelin *et al.*, 1994) (Fig. 8.10). It also is a ligand for cell surface receptors and regulates cell proliferation and migration (Tammi *et al.*, 2002; Turley *et al.*, 2002). One receptor for hyaluronan is the transmembrane molecule CD44. By alternative splicing and variations in post-translational modifications, a family of CD44 proteins is generated (Lesley *et al.*, 1993). These show cell- and tissue-

specific expression patterns and are thought to have distinct functional roles. Hyaluronan-mediated cell motility is based on the interaction of hyaluronan with a cell surface-associated protein called RHAMM (receptor for hyaluronate-mediated motility) (Nedvetzki *et al.*, 2004). As a space-filling molecule and through its interaction with cell surface receptors, hyaluronan is important for several morphogenetic processes during development. It creates cell free spaces through which cells (for example, neural crest cells) can migrate, and its degradation by hyaluronidase is probably important for processes of cellular condensation. Since hyaluronan is not immunogenic, is readily available, and can easily be manipulated and chemically modified, it is receiving considerable attention as a tissue-engineering biopolymer (Allison and Grande-Allen, 2006).

## VI. CONCLUSION

Research efforts since the mid-1970s have led to significant insights into the composition of extracellular matrices and the structure and function of the major components. We now realize that the evolution of vertebrates and mammals was associated with an expansion of several families of matrix molecules, providing cells with an increasing repertoire of isoforms and homologs to build different tissues. It is also evident that the increasing number of different families of genes encoding matrix molecules during evolution of more complex organisms involved shuffling and recombination of genes encoding a relatively small number of structural and functional modules. Finally, the data suggest that cells are building matrices by adding layer upon layer of components that can interact with various affinities (but mostly on the low side) and in multiple ways with their neighbors. The result is an extracellular matrix that readily can be fine-tuned to meet the demands of the moment, but one that is relatively resistant to the effects of mutations that may cause dysfunction of specific components. As we learn to use these insights to identify the most critical matrix properties from a cellular point of view, exciting and rapid advances in tissue engineering should follow.

### I. INTRODUCTION

*Morphogenesis* is the developmental cascade of pattern formation, the establishment of the body plan and architecture of mirror-image bilateral symmetry of musculoskeletal structures, culminating in the adult form. *Tissue engineering* is the emerging discipline of fabrication of spare parts for the human body, including the skeleton, for functional restoration and aging of lost parts due to cancer, disease, and trauma. It is based on rational principles of molecular developmental biology and morphogenesis and is further governed by bioengineering. The three key ingredients for both morphogenesis and tissue engineering are inductive morphogenetic signals, responding stem cells, and the extracellular matrix scaffolding (Reddi, 1998) (Fig. 9.1). Recent advances in molecular cell biology of morphogenesis will aid in the design principles and architecture for tissue engineering and regeneration.

The long-term goal of tissue engineering is to engineer functional tissues *in vitro* for implantation *in vivo* to repair, enhance, and replace, to preserve physiological function. Tissue engineering is based on the principles of develop-

mental biology, evolution and self-assembly of supramolecular assemblies and higher hierarchal tissues and even whole embryos and organisms (Figs. 9.2 and 9.3). Regeneration recapitulates embryonic development and morphogenesis. Among the many tissues in the human body, bone has considerable powers for regeneration and, therefore, is a prototype model for tissue engineering. On the other hand, articular cartilage, a tissue adjacent to bone, is recalcitrant to repair and regeneration. Implantation of demineralized bone matrix into subcutaneous sites results in local bone induction. The sequential cascade of bone morphogenesis mimics sequential skeletal morphogenesis in limbs and permits the isolation of bone morphogens. Although it is traditional to study morphogenetic signals in embryos, bone morphogenetic proteins (BMPs), the primordial inductive signals for bone were isolated from demineralized bone matrix from adults. BMPs initiate, promote, and maintain chondrogenesis and osteogenesis and have actions beyond bone. The recently identified cartilage-derived morphogenetic proteins (CDMPs) are critical for cartilage and joint morphogenesis. The symbiosis of bone inductive and con-

### KEY INGREDIENTS FOR TISSUE ENGINEERING

- Morphogenetic Signals
- Responding Stem Cells
- Extracellular Matrix Scaffolding

**FIG. 9.1.** The tissue-engineering triad consists of signals, stem cells, and scaffolding.

**FIG. 9.3.** Developmental origins of skeleton in the chick embryo. The cranial neural crest gives rise to craniofacial skeleton. The lateral plate mesoderm gives rise to the limbs of the appendicular skeleton. The sclerotome of the somite gives rise to spine and the axial skeleton.

**FIG. 9.2.** Evolution of skeletal structures in a variety of mammals adapted for flight (bat, A) and aquatic life (whale, B) and the use of hands in humans (H).

ductive strategies is critical for tissue engineering and is in turn governed by the context and biomechanics. The context is the microenvironment, consisting of extracellular matrix scaffolding, and can be duplicated by biomimetic biomaterials, such as collagens, hydroxyapatite, proteoglycans, and cell adhesion proteins, including fibronectins and laminins. The rules of architecture for tissue engineering are an imitation and adoption of the laws and signals of developmental biology and morphogenesis, and thus they may be universal

for all tissues, including bones and joints and associated musculoskeletal tissues in the limbs.

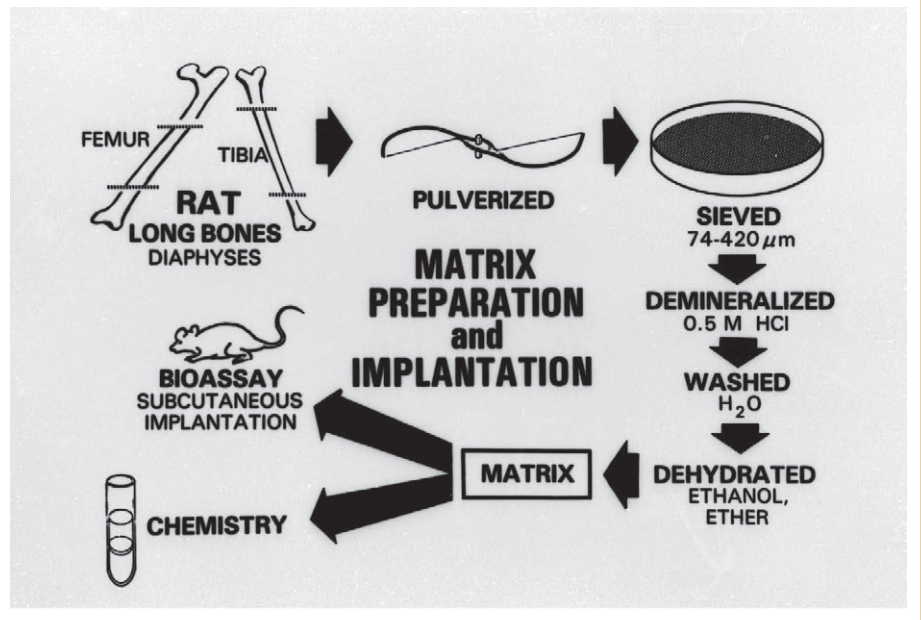

The traditional approach for identification and isolation of morphogens is first to identify genes in fly and frog embryos by means of genetic approaches, differential displays, subtractive hybridization, and expression cloning. This information is subsequently extended to mice and men. An alternative approach is to isolate morphogens from bone, the premier tissue with the highest regenerative potential. Morphogenesis is the developmental cascade of pattern formation, the establishment of the body plan and architecture of mirror-image bilateral symmetry of musculoskeletal structures in the appendicular skeleton, culminating in the adult form. The expanding knowledge in bone and cartilage morphogenesis is a prototypical paradigm for all of tissue engineering. The principles gleaned from bone morphogenesis and BMPs can be extended to tissue engineering of bone and cartilage and other tissues.

## II. BONE MORPHOGENETIC PROTEINS (BMPs)

Bone grafts have been used by orthopedic surgeons for nearly a century to aid and abet recalcitrant bone repair. Decalcified bone implants have been used to treat patients with osteomyelitis (Senn, 1989). It was hypothesized that bone might contain a substance, osteogenin, that initiates bone growth (Lacroix, 1945). Urist (1965) made the key discovery that demineralized, lyophilized segments of rabbit bone, when implanted intramuscularly, induced new bone formation. The diaphysis (shafts) of long bones of rats were cleaned of marrow, pulverized, and sieved. The demineralization of matrix was accomplished by 0.5 M HCl (Fig. 9.4). Bone induction, a sequential multistep cascade, is depicted in Fig. 9.5 (Reddi and Huggins, 1972; Reddi and Anderson, 1976; Reddi, 1981). The key steps in this cascade are chemotaxis, mitosis, and differentiation. Chemotaxis is the directed migration of cells in response to a chemical gradient of signals released from the insoluble demineralized bone

## Matrix Preparation

**FIG. 9.4.** Preparation of the demineralized bone matrix (DBM). The diaphysis (shafts) of femur and tibia are cleansed of marrow and dried prior to pulverization. The pulverized bone matrix is sieved to a particle size of 74–420 μm and demineralized by 0.5 M HCl, dehydrated in ethanol and diethyl ether. The resulting matrix is a potent inducer of cartilage and bone, and we isolate, by means of chemical techniques, the active osteoinductive agent BMP.

matrix. The demineralized bone matrix is composed predominantly of type I insoluble collagen, and it binds plasma fibronectin (Weiss and Reddi, 1980). Fibronectin has domains for binding to collagen, fibrin, and heparin. The responding mesenchymal cells attached to the collagenous matrix and proliferated as indicated by [<sup>3</sup>H]thymidine autoradiography and incorporation into acid-precipitable DNA on day 3 (Rath and Reddi, 1979). Chondroblast differentiation was evident on day 5, chondrocytes on days 7–8, and cartilage hypertrophy on day 9 (Fig. 9.5). Vascular invasion was concomitant on day 9 with osteoblast differentiation. On days 10–12 alkaline phosphatase was maximal. Osteocalcin, bone γ-carboxyglutamic acid containing gla protein (BGP), increased on day 28. Hematopoietic marrow differentiated in the ossicle and was maximal by day 21. This entire sequential bone development cascade is reminiscent of bone and cartilage morphogenesis in the limb bud (Reddi, 1981, 1984). Hence, it has immense implications for isolation of inductive signals initiating cartilage and bone morphogenesis. In fact, a systematic investigation of the chemical components responsible for bone induction was undertaken.

The foregoing account of the demineralized bone matrix-induced bone morphogenesis in extraskeletal sites demonstrated the potential role of morphogens tightly associated with the extracellular matrix. Next, we embarked on a systematic study of the isolation of putative morphogenetic proteins. A prerequisite for any quest for novel morphogens is the establishment of a battery of bioassays for new bone formation. A panel of *in vitro* assays were estab-

lished for chemotaxis, mitogenesis, and chondrogenesis, and an *in vivo* bioassay was established for bone formation. Although the *in vitro* assays are expedient, we monitored routinely a labor-intensive *in vivo* bioassay, for it was the only bona fide bone induction assay.

A major stumbling block in the approach was that the demineralized bone matrix is insoluble and is in the solid state. In view of this, dissociative extractants such as 4 M guanidine HCl or 8 M urea as 1% sodium dodecyl sulfate (SDS) at pH 7.4 were used (Sampath and Reddi, 1981) to solubilize proteins. Approximately 3% of the proteins were solubilized from demineralized bone matrix, and the remaining residue was mainly insoluble type I bone collagen. The extract alone or the residue alone was incapable of new bone induction. However, addition of the extract to the residue (insoluble collagen) and then implantation in a subcutaneous site resulted in bone induction (Fig. 9.6). Thus, it would appear that for optimal osteogenic activity there was a collaboration between the soluble signal in the extract and insoluble substratum or scaffolding (Sampath and Reddi, 1981). Thus, an operational concept of tissue engineering was established that soluble signals bound to extracellular matrix scaffold act on responding stem/progenitor cells to induce tissue digestion. This bioassay was a useful advance in the final purification of bone morphogenetic proteins and led to the determination of limited tryptic peptide sequences leading to the eventual cloning of BMPs (Wozney *et al.*, 1988; Luyten *et al.*, 1989; Ozkaynak *et al.*, 1990).

In order to scale up the procedure, a switch was made to bovine bone. Demineralized bovine bone was not osteo-

## Sequential Cascade

**FIG. 9.5.** Developmental sequence of extracellular matrix-induced cartilage, bone, and marrow formation. Changes in  $^{35}\text{SO}_4$  incorporation into proteoglycans and  $^{45}\text{Ca}$  incorporation into the mineral phase indicate peaks of cartilage and bone formation, respectively. The  $^{59}\text{Fe}$  incorporation into heme is an index of erythropoiesis, as plotted from the data of Reddi and Anderson (1976). The values for alkaline phosphatase indicate early stages of bone formation (Reddi and Huggins 1972). The transitions in collagen types I to IV, summarized on top of the figure, are based on immunofluorescent localization = polymorphonuclear leukocytes. (Source: Reddi (1981), with permission.)

## Dissociative Extraction and Reconstitution

**FIG. 9.6.** Dissociative extraction by chaotropic reagents such as 4 M guanidine and reconstitution of osteoinductive activity with insoluble collagenous matrix. The results demonstrate a collaboration between a soluble signal and insoluble extracellular matrix. This experiment further established the basic tenets of tissue engineering in 1981 as signals, scaffolds, and responding stem cells.

inductive in rats, and the results were variable. However, when the guanidine extracts of demineralized bovine bone were fractionated on an S-200 molecular sieve column, fractions less than 50 kD were consistently osteogenic when bioassayed after reconstitution with allogeneic insoluble collagen (Sampath and Reddi, 1983; Reddi, 1994). Thus, protein fractions inducing bone were not species specific and appear to be homologous in several mammals. It is likely that larger molecular mass fractions and/or the insoluble xenogeneic (bovine and human) collagens were inhibitory or immunogenic. Initial estimates revealed 1  $\mu\text{g}$  of active osteogenic fraction in a kilogram of bone. Hence, over a ton of bovine bone was processed to yield optimal amounts for amino acid sequence determination. The amino acid sequences revealed homology to TGF- $\beta_1$  (Reddi, 1994). The important work of Wozney and colleagues (1988) cloned BMP-2, BMP-2B (now called BMP-4), and BMP-3 (also called osteogenin). Osteogenic protein-1 and -2 (OP-1 and OP-2) were cloned by Ozkaynak and colleagues (1990). There are nearly 10 members of the BMP family (Table 9.1). The other members of the extended TGF- $\beta$ /BMP superfamily include inhibins and activins (implicated in follicle-stimulating hormone release from pituitary), Müllerian duct inhibitory substance (MIS), growth/differentiation factors (GDFs), nodal, and lefty, a gene implicated in establishing right/left asymmetry (Reddi, 1997; Cunningham *et al.*, 1995). BMPs are also involved in embryonic induction (Lemaire and Gurdon, 1994; Melton 1991; Lyons *et al.*, 1995; Reddi, 1997).

**Table 9.1. Bone morphogenetic proteins**

<i>BMP</i>	<i>Other names</i>	<i>Function</i>
BMP-2	BMP-2A	Bone and cartilage morphogenesis
BMP-3	Osteogenin	Bone morphogenesis
BMP-3B	GDF-10	Intramembranous bone formation
BMP-4	BMP-2B	Bone morphogenesis
BMP-5		Bone morphogenesis
BMP-6		Cartilage hypertrophy
BMP-7	Osteogenic protein-1	Bone formation
BMP-8	Osteogenic Protein-2	Bone formation
BMP-8B		Spermatogenesis
BMP-9		Liver differentiation
BMP-10		?
		Tooth differentiation
BMP-11	GDF-11	Odontoblast regulation
BMP-15		?

BMPs are dimeric molecules, and the conformation is critical for biological actions. Reduction of the single inter-chain disulfide bond resulted in the loss of biological activity. The mature monomer molecule consists of about 120 amino acids, with seven canonical cysteine residues. There are three intrachain disulfides per monomer and one inter-chain disulfide bond in the dimer. In the critical core of the BMP monomer is the cysteine knot. The crystal structure of BMP-7 has been determined (Griffith *et al.*, 1996). It is a good possibility that in the near future the crystal structure of BMP-receptor and receptor contact domains will be determined (Griffith *et al.*, 1996).

### III. CARTILAGE-DERIVED MORPHOGENETIC PROTEINS (CDMPs)

Morphogenesis of the cartilage is the key rate-limiting step in the dynamics of bone development. Cartilage is the initial model for the architecture of bones. Bone can form either directly from mesenchyme, as in intramembranous bone formation, or with an intervening cartilage stage, as in endochondral bone development (Reddi, 1981). All BMPs induce, first, the cascade of chondrogenesis, and therefore in this sense they are cartilage morphogenetic proteins. The hypertrophic chondrocytes in the epiphyseal growth plate mineralize and serve as a template for appositional bone morphogenesis. Cartilage morphogenesis is critical for both bone and joint morphogenesis. The two lineages of cartilage are clear-cut. The first, at the ends of bone, forms articulating articular cartilage. The second is the growth plate chondrocytes, which, through hypertrophy, synthesize cartilage

**Table 9.2. Cartilage-derived morphogenetic proteins**

<i>CDMP</i>	<i>Other names</i>	<i>Function</i>
CDMP 1	GDF-5	Cartilage condensation
CDMP 2	GDF-6	Cartilage formation, hypertrophy
CDMP 3	GDF-7	Tendon/ligament morphogenesis

matrix destined to calcify prior to replacement by bone, and are the “organizer” centers of longitudinal and circumferential growth of cartilage, setting into motion the orderly program of endochondral bone formation. The phenotypic stability of the articular (permanent) cartilage is at the crux of the osteoarthritis problem. The maintenance factors for articular chondrocytes include TGF- $\beta$  isoforms and the BMP isoforms (Luyten *et al.*, 1992).

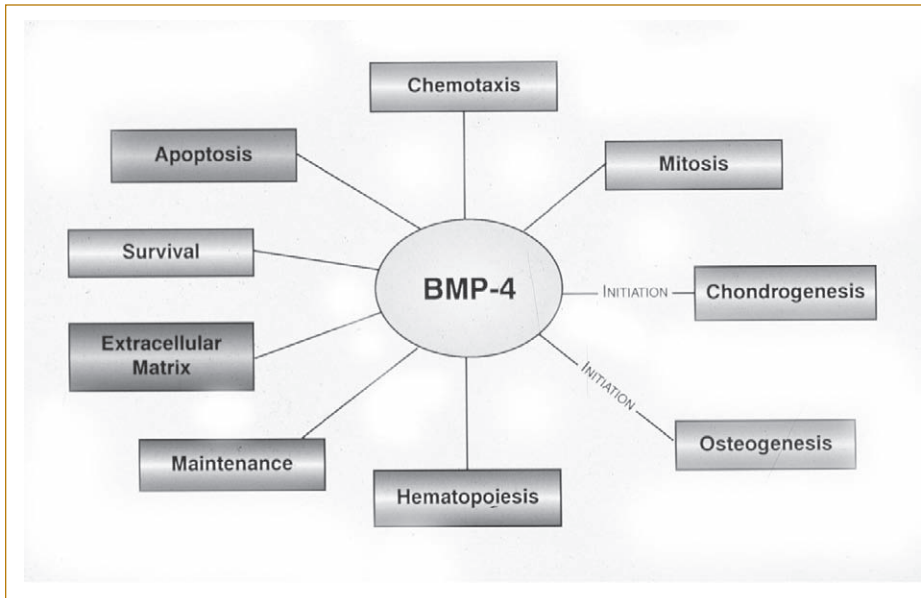

An *in vivo* chondrogenic bioassay with soluble purified proteins and insoluble collagen scored for chondrogenesis. A concurrent reverse transcription–polymerase chain reaction (RT-PCR) approach was taken with degenerate oligonucleotide primers. Two novel genes for cartilage-derived morphogenetic proteins (CDMPs) 1 and 2 were identified and cloned (Chang *et al.*, 1994). CDMPs 1 and 2 are also called GDF-5 and GDF-6 (Storm *et al.*, 1994). CDMPs are related to bone morphogenetic proteins (Table 9.2). CDMPs are critical for cartilage and joint morphogenesis (Tsumaki *et al.*, 1999). CDMPs stimulate proteoglycan synthesis in cartilage. CDMP 3 (also known as GDF-7) initiates tendon and ligament morphogenesis (Wolfman *et al.*, 1998).

### IV. PLEIOTROPY AND THRESHOLDS

Morphogenesis is a sequential multistep cascade. BMPs regulate each of the key steps: chemotaxis, mitosis, and differentiation of cartilage and bone (Fig. 9.7). BMPs initiate chondrogenesis in the limb (S. Chen *et al.*, 1991; Duboule, 1994). The apical ectodermal ridge is the source of BMPs in the developing limb bud. The intricate dynamic, reciprocal interactions between the ectodermally derived epithelium and mesodermally derived mesenchyme sets into motion the train of events culminating in the pattern of phalanges, radius, ulna, and the humerus.

The chemotaxis of human monocytes is optimal at femtomolar concentration (Cunningham *et al.*, 1992). The apparent affinity was 100–200 pM. The mitogenic response was optimal at the 100-pM range. The initiation of differentiation was in the nanomolar range in solution. However, caution should be exercised, because BMPs may be sequestered by extracellular matrix components, and the local concentration may be higher when BMPs are bound on the extracellular matrix. A single recombinant BMP human 4 can govern chemotaxis and mitosis differentiation of cartilage and bone, maintain phenotype, stimulate extracellular

**FIG. 9.7.** BMPs are pleiotropic molecules. Pleiotropy is the property of a single gene or protein to act on a multiplicity of cellular phenomena and targets.

matrix, and promote survival of some cells but cause the death of others (Fig. 9.7). Thus BMPs are pleiotropic regulators that act in concentration-dependent thresholds.

## V. BMPs BIND TO EXTRACELLULAR MATRIX

It is well known that extracellular matrix components play a critical role in morphogenesis. The structural macromolecules and their supramolecular assembly in the matrix do not explain their role in epithelial–mesenchymal interaction and morphogenesis. This riddle can now be explained by the binding of bone morphogenetic proteins to heparan sulfate heparin and type IV collagen (Paralkar *et al.*, 1990, 1991, 1992) of the basement membranes. In fact, this might explain in part the necessity for angiogenesis prior to osteogenesis during development. In addition, the actions of activin in development of the frog, in terms of dorsal mesoderm induction, is modified to neuralization by follistatin (Hemmati-Brivanlou *et al.*, 1994). Similarly, Chordin and Noggin from the Spemann organizer induce neuralization via binding and inactivation of BMP-4 (Fig. 9.2). Thus neural induction is likely to be a default pathway when BMP-4 is nonfunctional (Piccolo *et al.*, 1996; Zimmerman *et al.*, 1996). Thus, an emerging principle in development and morphogenesis is that binding proteins can terminate a dominant morphogen's action and initiate a default pathway. Finally, the binding of a soluble morphogen to extracellular matrix converts it into an insoluble matrix-bound morphogen to act locally in the solid state (Paralkar *et al.*, 1990).

Although BMPs were isolated and cloned from bone, work with gene knockouts have revealed a plethora of actions beyond bone. Mice with targeted disruption of BMP-2 caused embryonic lethality. The heart development is

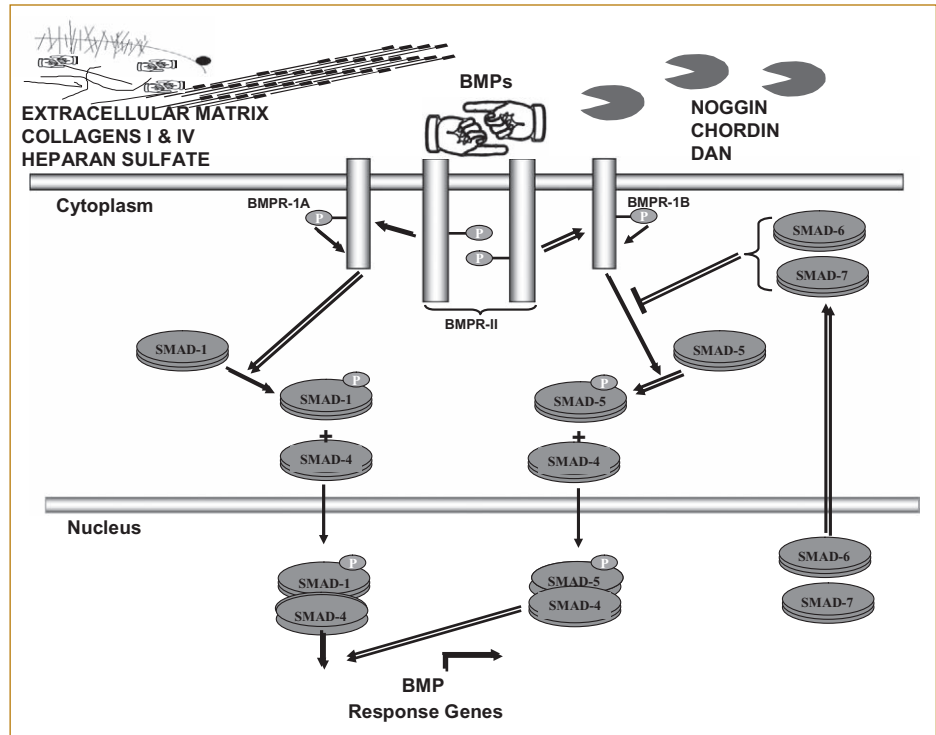

abnormal, indicating a need for BMP-2 in heart development (Zhang and Bradley, 1996). BMP-4 knockouts exhibit no mesoderm induction, and gastrulation is impaired (Winnier *et al.*, 1996). Transgenic overexpression of BMPs under the control of keratin 10 promoter leads to psoriasis. The targeted deletion of BMP-7 revealed the critical role of this molecule in kidney and eye development (Luo *et al.*, 1995; Dudley *et al.*, 1995; Vukicevic *et al.*, 1996). Thus the BMPs are really true morphogens for such disparate tissues as skin, heart, kidney, and eye. In view of this, BMPs may also be called body morphogenetic proteins (Reddi, 2005).

## VI. BMP RECEPTORS

Recombinant human BMP-4 and BMP-7 bind to BMP receptor IA (BMPR-IA) and BMP receptor IB (BMPR-IB) (ten Dijke *et al.*, 1994). CDMP-1 also binds to both type I BMP receptors. There is a collaboration between type I and type II BMP receptors (Nishitoh *et al.*, 1996). The type I receptor serine/threonine kinase phosphorylates a signal-transducing protein substrate called Smad 1 or 5 (S. Chen *et al.*, 1996). *Smad* is a term derived from the fusion of the *Drosophila* Mad gene and the *Caenorhabditis elegans* (nematode) Sma gene. Smads 1 and 5 signal in partnership with a common co-Smad, Smad 4 (Fig. 9.8). The transcription of BMP-response genes are initiated by Smad 1/Smad 4 heterodimers. Smads are trimeric molecules, as gleaned via x-ray crystallography. The phosphorylation of Smads 1 and 5 by type I BMP receptor kinase is inhibited by inhibitory Smads 6 and 7 (Hayashi *et al.*, 1997). Smad-interacting protein (SIP) may interact with Smad 1 and modulate BMP-response gene expression (Heldin *et al.*, 1997; Reddi, 1997; Miyazono *et al.*, 2005). The downstream targets of BMP signaling are likely to be homeobox genes, the cardinal genes for morphogenesis and transcription. BMPs in turn may be

**FIG. 9.8.** BMP receptors and signaling cascades. BMPs are dimeric ligands with cysteine knot in each monomer fold. Each monomer has two  $\beta$ -sheets, represented as two pointed fingers. In the functional dimer, the fingers are oriented in opposite directions. BMPs interact with both type I and II BMP receptors. The exact stoichiometry of the receptor complex is currently being elucidated. BMPR-II phosphorylates the GS domain of BMPR-I. The collaboration between type I and II receptors forms the signal-transducing complex. BMP type I receptor kinase complex phosphorylates the trimeric signaling substrates Smad 1 and Smad 5. This phosphorylation is inhibited and modulated by inhibitory Smads 6 and 7. Phosphorylated Smad 1 or 5 interacts with Smad 4 (functional partner) and enters the nucleus to activate the transcriptional machinery for early BMP-response genes. A novel Smad-interacting protein (SIP) may interact and modulate the binding of heteromeric Smad 1/Smad 4 complexes to the DNA.

regulated by members of the hedgehog family of genes, such as Sonic and Indian hedgehog (Johnson and Tabin, 1997), including receptors patched and smoothed and transcription factors such as Gli 1, 2, and 3. The actions of BMPs can be terminated by specific binding proteins, such as noggin (Zimmerman *et al.*, 1996).

## VII. RESPONDING STEM CELLS

It is well known that the embryonic mesoderm-derived mesenchymal cells are progenitors for bone, cartilage, tendons, ligaments, and muscle. However, certain stem cells in adult bone marrow, muscle, and fascia can form bone and cartilage. The identification of stem cells readily sourced from bone marrow may lead to banks of stem cells for cell therapy and perhaps gene therapy with appropriate “homing” characteristics to bone marrow and hence to the skeleton. The pioneering work of Friedenstein *et al.* (1968) and Owen and Friedenstein (1988) identified bone marrow stromal stem cells. These stromal cells are distinct from the hematopoietic stem cell lineage. The bone marrow stromal stem cells consist of inducible and determined osteoprogenitors committed to osteogenesis. Determined osteogenic precursor cells have the propensity to form bone cells, without any external cues or signals. On the other hand, inducible osteogenic precursors require an inductive signal, such as BMP or demineralized bone matrix. It is noteworthy that operational distinctions between stromal stem cells and hematopoietic stem cells are getting more and more blurry! The stromal stem cells of Friedenstein and Owen are also called mesenchymal stem cells (Caplan, 1991), with

potential to form bone, cartilage, adipocytes, and myoblasts in response to cues from the environment and/or intrinsic factors. There is considerable hope and anticipation that these bone marrow stromal cells may be excellent vehicles for cell and gene therapy (Prockop, 1997).

From a practical standpoint, these stromal stem cells can be obtained by bone marrow biopsies and expanded rapidly for use in cell therapy after pretreatment with bone morphogenetic proteins. The potential uses in both cell and gene therapy is very promising. There are continuous improvements in the viral vectors and efficiency of gene therapy (Bank, 1996; Mulligan, 1993). For example, it is possible to use BMP genes transfected in stromal stem cells to target the bone marrow.

## VIII. MORPHOGENS AND GENE THERAPY

The recent advances in morphogens are ripe for techniques of regional gene therapy for orthopedic tissue engineering. The availability of cloned genes for BMPs and CDMPs and the requisite platform technology of gene therapy may have immediate applications. Whereas protein therapy provides an immediate bolus of morphogen, gene therapy achieves a sustained, prolonged secretion of gene products. Furthermore, recent improvements in regulated gene expression allows the turning on and off of gene expression. The progress in vectors for delivering genes also bodes well. The use of adenoviruses, adeno-associated viruses, and retroviruses is poised for applications in bone and joint repair (Bank, 1996; Kozarsky and Wilson, 1993; Morsy *et al.*, 1993; Mulligan, 1993). Although gene therapy

has some advantages for orthopedic tissue engineering, an optimal delivery system for protein and gene therapy is needed, especially in the replacement of large segmented defects and in fibrous nonunions and malunions.

## IX. BIOMIMETIC BIOMATERIALS

Our earlier discussions of inductive signals (BMPs) and responding stem cells (stromal cells) lead us to the scaffolding (the microenvironment/extracellular matrix) for optimal tissue engineering. The natural biomaterials in the composite tissue of bones and joints are collagens, proteoglycans, and glycoproteins of cell adhesion, such as fibronectin and the mineral phase. The mineral phase in bone is predominantly hydroxyapatite. In native state, the associated citrate, fluoride, carbonate, and trace elements constitute the physiological hydroxyapatite. The high protein-binding capacity makes hydroxyapatite a natural delivery system. Comparison of insoluble collagen, hydroxyapatite, tricalcium phosphate, glass beads, and polymethylmethacrylate as carriers revealed collagen to be an optimal delivery system for BMPs (Ma *et al.*, 1990). It is well known that collagen is an ideal delivery system for growth factors in soft and hard tissue wound repair (McPherson, 1992). Hydrogels may be of great utility in cartilage tissue engineering (Fisher *et al.*, 2004).

During the course of systematic work on hydroxyapatite of two pore sizes (200 or 500  $\mu\text{m}$ ) in two geometrical forms (beads or discs), an unexpected observation was made. The geometry of the delivery system is critical for optimal bone induction. The discs were consistently osteoinductive with BMPs in rats, but the beads were inactive (Ripamonti *et al.*, 1992). The chemical composition of the two hydroxyapatite configurations were identical. In certain species, the hydroxyapatite alone appears to be “osteoinductive” (Ripamonti, 1996). In subhuman primates, the hydroxyapatite induces bone, albeit at a much slower rate. One interpretation is that osteoinductive endogenous BMPs in circulation progressively bind to an implanted disc of hydroxyapatite. When an optimal threshold concentration of native BMPs is achieved, the hydroxyapatite becomes osteoinductive. Strictly speaking, most hydroxyapatite substrata are ideal osteoconductive materials. This example in certain species also serves to illustrate how an osteoconductive biomimetic biomaterial can progressively function as an osteoinductive substance by binding to endogenous BMPs. Thus, there is a physiological-physicochemical continuum between the hydroxyapatite alone and progressive composites with endogenous BMPs. Recognition of this experimental nuance will save unnecessary arguments among biomaterials scientists about the osteoinductive action of a conductive substratum such as hydroxyapatite.

Complete regeneration of baboon craniotomy defect was accomplished via recombinant human osteogenic protein (rhOP-1; human BMP-7) (Ripamonti *et al.*, 1996). Recombinant BMP-2 was delivered by poly.( $\alpha$ -hydroxy acid) carrier for calvarial regeneration (Hollinger *et al.*, 1996).

Copolymer of polylactic acid and polyglycolic acid with recombinant BMP-2 were used in a nonunion model in rabbit ulna and complete unions were achieved in the bone (Bostrom *et al.*, 1996).

An important problem in the clinical application of biomimetic biomaterials with BMPs and/or other morphogens would be the sterilization. Although gas (ethylene oxide) is used, one should always be concerned about reactive free radicals. Using allogeneic demineralized bone matrix with endogenous native BMPs, as long as low temperature (4°C or less) is maintained, the samples tolerated up to 5–7 Mrads of irradiation (Weintraub and Reddi, 1988; Weintraub *et al.*, 1990). The standard dose acceptable to the Food and Drug Administration is 2.5 Mrads. This information would be useful to the biotechnology companies preparing to market recombinant BMP-based osteogenic devices. Perhaps, the tissue-banking industry, with its interest in bone grafts (Damien and Parson, 1991), could also use this critical information. The various freeze-dried and demineralized allogeneic bone may be used in the interim as satisfactory carriers for BMPs. The moral of this experiment is it is not the irradiation dose but the ambient sample temperature during irradiation that is absolutely critical.

## X. TISSUE ENGINEERING OF BONES AND JOINTS

Unlike bone, with its considerable prowess for repair and even regeneration, cartilage is recalcitrant. But why? In part this may be due to the relative avascularity of hyaline cartilage and the high concentration of protease inhibitors and perhaps even of growth inhibitors. The wound-debridement phase is not optimal for preparing the cartilage wound bed for the optimal *milieu interieur* for repair. Although cartilage has been successfully engineered to predetermined shapes (Kim *et al.*, 1994), true repair of the tissue continues to be a real challenge, in part due to hierarchical organization and geometry (Mow *et al.*, 1992). However, considerable excitement in the field has been generated by a group of Swedish workers in Göteborg, using autologous culture-expanded human chondrocytes (Brittberg *et al.*, 1994). A continuous challenge in chondrocyte cell therapy is progressive dedifferentiation and loss of characteristic cartilage phenotype. The redifferentiation and maintenance of the chondrocytes for cell therapy can be aided by BMPs, CDMPs, TGF- $\beta$  isoforms, and IGFs. It is also possible to repair cartilage using muscle-derived mesenchymal stem cells (Grande *et al.*, 1995). The potential possibility of the problems posed by cartilage proteoglycans in preventing cell immigration for repair was investigated by means of chondroitinase ABC and trypsin pretreatment in partial-thickness defects (Hunziker and Rosenberg, 1996), with and without TGF. Pretreatment with chondroitinase ABC followed by TGF revealed a contiguous layer of cells from the synovial membrane, hinting at the potential source of repair

**FIG. 9.9.** Repair of segmental defects in a primate bone by means of recombinant human BMP-7 and collagenous matrix scaffold. (Photographs provided by Dr. T. K. Sampath.)

cells from synovium. Multiple avenues of cartilage morphogens, cell therapy with chondrocytes and stem cells from marrow and muscle, and a biomaterial scaffolding may lead to an optimal tissue-engineered articular cartilage.

Recombinant human BMP-2 and BMP-7 were approved in 2002 by the Food and Drug Administration (FDA) for tibial nonunions and single-level spine fusion. BMPs have been used in healing segmental defects (Fig. 9.9). The proof of the principles of tissue engineering based on BMPs as signals, mold of a scaffold, and responding cells can be demonstrated (Fig. 9.10).

## XI. FUTURE CHALLENGES

It is inevitable during the aging of humans that one will confront impaired locomotion due to wear and tear in bones and joints. Therefore, the repair and possibly complete regeneration of the musculoskeletal system and other vital organs, such as skin, liver, and kidney, may potentially need optimal repair or a spare part for replacement. Can we create spare parts for the human body? There is much reason for optimism that tissue engineering can help patients. We are living in an extraordinary time with regard to biology, medicine, surgery, bioengineering, computer modeling of predictive tissue engineering, and technology. The confluence of advances in molecular developmental biology and attendant advances in inductive signals for morphogenesis, stem cells, biomimetic biomaterials, and extracellular matrix biology augers well for imminent breakthroughs.

The symbiosis of biotechnology and biomaterials has set the stage for systematic advances in tissue engineering

## Tissue Engineering: Proof of Principle

**FIG. 9.10.** Proof of the principles of tissue engineering was established *in vivo* by Khouri *et al.* (1991). A mold was used to contain the vascularized muscle flap and treated with purified BMPs and collagen scaffold. The newly formed bone faithfully reproduced the shape of the mold. In the future, one can use stem cells directed by recombinant BMPs to induce bone.

(Reddi, 1994; Langer and Vacanti, 1993; Hubbel, 1995). The recent advances in enabling platform technology includes molecular imprinting (Mosbach and Ramstrom, 1996). In principle, specific recognition and catalytic sites are imprinted using templates. The applications include biosensors, catalytic applications to antibody, and receptor recognition sites. For example, the cell-binding RGD site in fibronectin (Ruoslahti and Pierschbacher, 1987) or the YIGSR domain in laminin can be imprinted in complementary sites (Vukicevic *et al.*, 1990).

The rapidly advancing frontiers in morphogenesis with BMPs, hedgehogs, homeobox genes, and a veritable cornucopia of general and specific transcription factors, co-activators, and repressors will lead to cocrystallization of ligand–receptor complexes, protein–DNA complexes, and other macromolecular interactions. This will lead to peptidomimetic agonists for large proteins, as exemplified by erythropoietin (Livnah *et al.*, 1996). To such advances one can add new developments in self-assembly of millimeter-scale structures floating at the interface of perfluorodecalin and water and interacting by means of capillary forces controlled by the pattern of wettability (Bowden *et al.*, 1997). The final self-assembly is due to minimization of free energy in the interface. These are truly incredible advances that will lead to man-made materials that mimic extracellular matrix in tissues. Superimpose on such chemical progress a bio-

logical platform in a bone-and-joint mold. Let us imagine a head of the femur and a mold fabricated via computer-assisted design and manufacture. It faithfully reproduces the structural features and may be imprinted with morphogens, inductive signals, and cell adhesion sites. This assembly can be loaded with stem cells and BMPs and other inductive signals, with a nutrient medium optimized for the number of cell cycles, and then it predictably exits into the differentiation phase to reproduce a totally new bone femoral head. In fact, such a biological approach with vascularized muscle flap and BMPs yielded new bone with a defined shape and has demonstrated proof of the principle for further development and validation (Khoury *et al.*, 1991). We indeed are entering a brave new world of prefabricated biological spare parts for the human body, based on sound architectural rules of inductive signals for morphogenesis, responding stem cells with lineage control, and with growth factors immobilized on a template of biomimetic biomaterial based on extracellular matrix. Like life itself, such technologies evolve with continuous refinements to benefit humankind by reducing the agony of human pain and suffering. In conclusion, based on principles of evolution, development, and self-assembly, the fields of tissue engineering and regenerative medicine are poised to make explosive advances with immense applications in the clinic.

### I. INTRODUCTION

Studies of skeletal muscle development were the first to provide the principles for understanding the genetic and molecular bases of determination and differentiation. Molecular signals from adjacent embryonic structures activate specific genetic pathways within target cells. Important families of transcriptional regulators are expressed in response to these cues to initiate these important developmental processes in skeletal muscle as well as in other tissues and organs. Both activators and repressors are essential to control the time and location at which development occurs, and self-regulating, positive feedback loops assure that once begun development can proceed normally. An understanding of the mechanistic basis of embryonic commitment to a unique developmental pathway, and the subsequent realization of the adult phenotype, are essential for understanding stem cell behavior and how they might be manipulated for therapeutic goals.

This chapter focuses on determination and differentiation, classical embryological concepts that emerged from descriptive embryology. It has been through the study of

muscle development that the genetic basis of these processes was first revealed, laying a mechanistic basis for understanding determination and differentiation. Following the success in studies of skeletal muscle (reviewed in Berkes and Tapscott, 2005; Brand-Saberi, 2005), genetic pathways involved in the determination of other systems, some of which are detailed in other chapters, have also been uncovered, largely because of the underlying conservation of structure among the various effector molecules and mechanisms.

### II. DETERMINATION AND DIFFERENTIATION

Determination describes the process whereby a cell becomes committed to a unique developmental pathway, which, under conditions of normal development, appears to be a stable state. In many cases cells become committed early in development yet remain highly proliferative, expanding exponentially for long periods of time before differentiation occurs. Until recently, determination could

**FIG. 10.1.** The process of commitment and differentiation. Cells arise during gastrulation in the vertebrate embryo that subsequently produce all the different cell type of the body. Cells that can be designated as mesenchymal stem cells (MSC) proliferate and, in response to cues from the cellular environment, enter lineages that undergo differentiation and subsequent maturation into the mature cell types.

only be defined post hoc. Prior to the discovery of transcriptional regulators there were few markers to indicate whether or not a cell was committed to a unique phenotype. Thus *determination* was operationally defined as that state that existed immediately prior to differentiation, that is, before expression of a cell type-specific phenotype. The identification of transcription factors that control the differential expression of large families of genes changed this concept.

Determination and differentiation are processes that are coupled during embryogenesis, where a small number of pluripotent cells (stem cells), expand and enter pathways where they form the diverse cell types of the adult. The process of differentiation describes the acquisition of the phenotype of a cell, most often identified by the expression of specific proteins achieved as a result of differential gene expression. The differentiated state is easily determined by simple observation in most instances, because most differentiated cells display a unique phenotype as a result of the expression of specific structural proteins. Skeletal muscle cells are an extreme example of this, having a cytoplasmic matrix filled with highly ordered myosin, actin, and other contractile proteins within sarcomeres — the functional

units of contraction — giving the fibers their cross-striated pattern. As development proceeds, there is a gradual narrowing of the possible final cell phenotypes that individual cells can adopt, with the final cell fate (set of genes expressed) determined by factors both extrinsic and intrinsic to the cell (Fig. 10.1). Changes in gene expression responsible for directing cells to differentiate along particular developmental pathways result from a response to stimuli received from surrounding cells and the specific cellular phenotype of the cell itself at the time of interaction. For example, cells of recently formed somites have the potential to form either skeletal muscle or cartilage in response to adjacent tissues, and the fate adopted is a result of their location with respect to adjacent structures — the notochord, neural tube, and overlying ectoderm — that produce signaling molecules that determine phenotype (Borycki and Emerson, 2000). In addition to the activation of muscle-specific structural and enzyme-encoding genes, the differentiated state is maintained by the continued expression of specific regulatory transcription factors that can now be identified using modern tools of cellular and molecular biology, including monoclonal antibodies, antisense nucleic acid probes, and gene chip analyses.

Commitment and differentiation to a skeletal muscle fate begins in the somites of the early vertebrate embryo. Within the embryonic somites, two distinct anatomical regions contain muscle progenitors. Specified by signals from the adjacent structures, the dorsal portion of each somite forms an epithelial structure, the *dermomyotome*, which contains the precursor cells of all skeletal muscles that will form in the vertebrate body (with the exception of those found in the head). The medial portion of dermomyotome contains cells that form the axial musculature surrounding the vertebral column, while cells of the ventral-lateral portion of the dermomyotome undergo a process of delamination and migrate into the forming appendages to produce the appendicular musculature of the limbs and body wall. While the muscle fibers that form from the different regions of the somite are nearly indistinguishable, myogenesis in the axial and appendicular muscles is regulated by different effectors, demonstrating the complexity of determination and differentiation in the early embryo.

### III. MyoD AND THE bHLH FAMILY OF DEVELOPMENTAL REGULATORY FACTORS

It was not until late in the 20th century that experiments first demonstrated that cellular commitment to specific developmental fates could be determined by the expression of a single gene or a very small number of genes (O'Neill and Stockdale, 1974; Taylor and Jones, 1979; Konieczny and Emerson, 1984; Lassar *et al.*, 1986; Tapscott *et al.*, 1989). With improvements in tissue culture methods and rapid advances in molecular biology that permitted the introduction of foreign genes into mammalian cells, the first factor capable of specifying a cell to a particular cellular phenotype, MyoD, was isolated and characterized in the laboratory of Dr. Harold Weintraub (Davis *et al.*, 1987; Tapscott *et al.*, 1988). MyoD expression is specific to skeletal muscle, and introduction of MyoD cDNA into fibroblasts of the 10T1/2 cell line converts them at a high frequency into stable myoblasts, which in turn express skeletal muscle proteins. MyoD was only the first of a family of myogenic regulatory factors (MRFs) to be discovered; others include myf-5 (Arnold and Winter, 1998), myogenin (Wright *et al.*, 1989), and MRF4 (Rhodes and Konieczny, 1989; reviewed by Berkes and Tapscott, 2005). The importance of MyoD and myf-5 to the determination of skeletal muscle was demonstrated when double knockout of these two genes in transgenic mice resulted in a nearly complete absence of skeletal muscle (Rudnicki *et al.*, 1993).

MRF members share a common structure, a stretch of basic amino acids followed by a stretch of amino acids that form two amphipathic helices separated by an intervening loop (the helix-loop-helix (HLH) motif), and they are nuclear-located DNA-binding proteins that act as transcrip-

tional regulators (Berkes and Tapscott, 2005). Experiments have demonstrated that the basic amino acids are required for DNA binding and essential for the myogenic conversion of fibroblasts to muscle, while the HLH motif plays an essential role in the formation of heterodimers with other ubiquitously expressed HLH proteins (products of the E2a gene) as well as in DNA binding (Murre *et al.*, 1989).

Nature being conservative, it is not surprising that the bHLH motif was found in transcriptional factors regulating the determination of cell types other than muscle. Based on homology to MyoD, the transcription factor NeuroD was isolated by the Weintraub laboratory and shown to act as a neuronal determination factor (Lee *et al.*, 1995). Expression of NeuroD in presumptive epidermal cells of *Xenopus* embryos converted many into fully differentiated neurons. Interestingly, NeuroD also plays an important role in the differentiation of pancreatic endocrine cells (Naya *et al.*, 1997; Itkin-Ansari *et al.*, 2005). While NeuroD is involved primarily in neuronal differentiation and survival, neurogenin, whose expression precedes that of NeuroD in the embryo, functions more like a determination factor (Ma *et al.*, 1996). Overexpression of *Xenopus* neurogenin induces ectopic neurogenesis as well as ectopic expression of NeuroD. Additional bHLH family members, including HES, Math-5, and Mash-1, have been isolated and participate in the determination of neural cells as well.

Differences in the expression of various members of the neurogenic bHLH family help to explain the diversity of neuronal cell types. For example, genetic deletion of the Mash-1 gene eliminates sympathetic and parasympathetic neurons and enteric neurons of the foregut (Lo *et al.*, 1994), while knockout of NeuroD leads to a loss of pancreatic endocrine cells as well as cells of the central and peripheral nervous system (Naya *et al.*, 1997). In addition to the various bHLH activators, other homeodomain-containing transcription factors are required for specification of neuronal subtypes.

Because cardiac muscle has so much in common with skeletal muscle, including a large number of contractile proteins, an exhaustive search was made for MyoD family members in the heart. Surprisingly, MyoD family members were not found in the developing heart, and thus they play no part in the differentiation of cardiac muscle cells. However, a different family of bHLH-containing factors, including dHAND and eHAND, were found in the developing heart, autonomic nervous system, neural crest, and deciduum. In the heart these factors are important for cardiac morphogenesis and the specification of cardiac chambers (Srivastava *et al.*, 1995). Unlike their MyoD family cousins, neither of the HAND proteins plays a role in differentiation of cardiac muscle cells.

Acting as dominant negative regulators of the bHLH family of transcriptional regulators is a ubiquitously expressed family of proteins that contain the helix-loop-helix structure but lack the upstream run of basic amino

acids essential for specific DNA binding by MyoD family members. Termed *inhibitors of differentiation* (Id), these proteins can associate specifically with MyoD or products of the E2A gene and attenuate their ability to bind DNA by forming nonfunctional heterodimeric complexes (Benezra *et al.*, 1990). Id in proliferating myoblasts inhibit the terminal differentiation program by complexing with the E12/E47 protein until the cell receives an appropriate stimulus. Id levels decrease on terminal differentiation.

Neuronal development is also regulated in part by repressors of the neurogenic family of bHLH activators. The HES family of HLH-containing proteins is expressed in neural stem cells, where they maintain proliferation of neuronal precursors and prevent premature differentiation in cells expressing NeuroD and neurogenin. The interaction of unique sets of positively acting bHLH activators and negatively acting members of the HES family helps explain how different subsets of neurons undergo differentiation at different times during development so that the complex structure of the brain can be achieved (Hatakeyama *et al.*, 2004; Kageyama *et al.*, 2005).

#### IV. MEFs — COREGULATORS OF DEVELOPMENT

The myocyte enhancer factor 2 (MEF2) family of MADS-box regulatory factors, originally described by Olsen and colleagues (Gossett *et al.*, 1989), participate with MyoD family members to regulate skeletal muscle differentiation (Molkentin and Olson, 1996). By themselves, MEF2 factors do not specify the muscle fate, but they are present in early stages of development, where they interact with MyoD family members to initiate muscle cell specific-gene expression (Molkentin *et al.*, 1995).

MEF2 proteins are transcriptional activators that bind to A+T-rich DNA sequences found in many muscle-specific genes, including those encoding contractile proteins, muscle fiber enzymes, and the muscle differentiation factor myogenin. While some members of this MADS-box regulatory factor family show a nearly ubiquitous distribution among tissue types, a few show more restricted expression to striated muscle (Martin *et al.*, 1993).

Unable to act alone, MEF2 family members must physically interact with MyoD family members at their DNA-binding domains to positively regulate transcription of downstream muscle-specific differentiation genes (Yun and Wold, 1996). Additionally, the transcriptional activation of muscle-specific genes requires that either the MyoD or MEF2 protein provide a transcriptional activation domain. Interestingly, although the wide tissue distribution of some MEF2 family members suggested that they may act in combination with bHLH family members found in other cell types (such as neurogenin in neural precursors) to activate downstream genes (Molkentin and Olson, 1996), no evidence has been found to that effect.

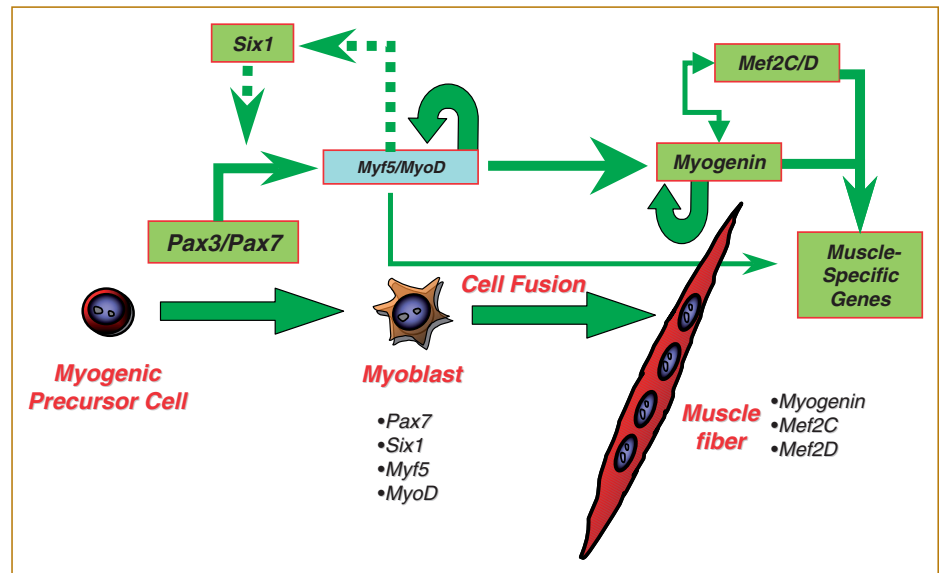

#### V. PAX IN DEVELOPMENT

Much of what has been learned about the role of MyoD and myf-5n in the determination of skeletal muscle has come from studies on transgenic mice in which various genetic loci have been deleted (Braun *et al.*, 1992; Rudnicki *et al.*, 1992; Hasty *et al.*, 1993; Nabeshima *et al.*, 1993; Rudnicki *et al.*, 1993; Tajbakhsh and Buckingham, 1994). This work suggested that MyoD and myf-5 acted as redundant activators of myogenesis, albeit with some slight distinctions. Subsequently, Pax3, a DNA-binding protein with both a paired box and a paired-type homeodomain, was identified as a key regulator of myogenesis (Goulding *et al.*, 1991; Relaix *et al.*, 2004). Double knockout of Pax3 and myf-5 leads to a complete absence of skeletal muscle and places Pax3 genetically upstream of MyoD (Tajbakhsh *et al.*, 1997). Using knock-in experiments where the lacZ marker gene replaced Pax3, Buckingham's group demonstrated that Pax3 and myf-5 are activated independent of one another. The implication is that axial muscle (myf-5-dependent) and appendicular muscle (MyoD-dependent) are specified separately in the embryonic somites by two different pathways (Hadchouel *et al.*, 2000, 2003) and that a Pax gene(s) is required for this specification (determination).

A second member of the paired box transcription factor family, Pax7, has also been implicated in myogenesis. Pax7 was isolated from satellite cells, a population of muscle-committed stem cells found in intimate association with mature muscle fibers and involved in muscle growth and repair in the adult. Pax7 is specifically expressed in proliferative myogenic precursors, both embryonic myoblasts as well as satellite cells, and is down-regulated at differentiation (Seale *et al.*, 2000). Transgenic mice lacking the Pax7 gene have normal musculature, albeit with reduced muscle mass, but a complete absence or markedly reduced numbers of satellite cells (Seale *et al.*, 2000; Relaix *et al.*, 2006). These investigators found that in these Pax7 mutants, satellite cells, cells responsible for postnatal growth of skeletal muscle, are progressively lost by cell death. These results suggest that specification of skeletal muscle satellite cells requires Pax7 expression or that Pax7 expression is responsible for survival of satellite cells. The interplay of the many factors that control the initiation and maintenance of myogenesis are diagramed in Fig. 10.2.

#### VI. CONCLUSIONS

Determination and differentiation are in large part controlled by the expression of transcriptional regulators. The processes begin early in development and involve the formation of stem cells that become committed to specific pathways of regulated gene expression. The regulators responsible were first characterized in studies examining commitment to, and differentiation of, skeletal muscle, and muscle development serves as a model for the mechanisms involved. Some other developing organs, such as the central

**FIG. 10.2.** A regulatory network controls muscle cell differentiation. (Provided by Dr. Michael Rudnicki and modified.)

and peripheral nervous systems and the pancreas, employ very similar mechanisms and closely related members of the HLH family of proteins to drive development. However, for reasons that are not clear, other organs, such as the heart, in which cardiac cells express many of the same contractile protein genes as their skeletal muscle cousins, use other

mechanisms. As our understanding of the mechanisms and effectors of determination and differentiation during embryonic development increase, we will be better able to conceive and apply strategies to engineer stem cells, embryonic- or adult-derived, to address medical problems through transplantation.

### I. INTRODUCTION

Tissue engineering is a rapidly growing field that seeks to restore the function of diseased or damaged tissues through the use of implanted cells, biomaterials, and biologically active molecules. Within the context of many organ systems, such as the musculoskeletal and cardiovascular systems, tissue function has a large biomechanical component involving the transmission or generation of mechanical forces. For example, articular cartilage and cardiac tissue possess highly specialized structures and compositions that provide unique biomechanical properties required to move the limbs and circulate the blood. The loss of function of cartilage and cardiac tissue due to injury, disease, or aging accounts for a significant number of clinical disorders, at a tremendous social and economic cost (Praemer *et al.*, 1999; Thom *et al.*, 2006). Although different in many respects, cartilage and cardiac tissue share two features that are highly relevant to functional tissue engineering: (1) lack of intrinsic capacity for self-repair and (2) performance of critical biomechanical functions *in vivo*.

Despite many early successes, few engineered tissue products are available for clinical use, and significant challenges still remain in exploiting tissue-engineering technologies for the successful long-term repair of mechanically functional tissues. The precise reasons for graft failure in

experimental animal studies and preclinical trials are not fully understood, but they include a combination of factors that lead to the breakdown of repair tissues under conditions of physiologic loading. The magnitudes of stresses and frequency of loading that tissues are subjected to *in vivo* can be quite large, and few engineered tissue constructs possess the biomechanical properties to withstand such stresses at the time of implantation. For many native tissues, however, the potential range of *in vivo* stresses and strains are not well characterized, thus making it difficult to incorporate a true “safety factor” into the design criteria for engineered tissues. Furthermore, the challenge is not as simple as matching a single mechanical parameter, such as modulus or strength; instead most tissues possess complex viscoelastic, nonlinear, and anisotropic mechanical and physicochemical properties that vary with age, site, and other host factors. Finally, a number of complex interactions must be considered, for the graft and surrounding host tissues are expected to grow and remodel in response to their changing environments postimplantation (Badylak *et al.*, 2002).

An evolving discipline referred to as **functional tissue engineering** has sought to address these challenges by developing guidelines for rationally investigating the role of biological and mechanical factors in tissue engineering. A series of formal goals and principles for functional tissue

engineering have been proposed in a generalized format (Butler *et al.*, 2000; Guilak *et al.*, 2003). In brief, these guidelines include development of: (1) improved definitions of functional success for tissue engineering applications; (2) improved understanding of the *in vivo* mechanical requirements and intrinsic properties of native tissues; (3) improved understanding of the biophysical environment of cells within engineered constructs; (4) scaffold design criteria that aim to enhance cell survival, differentiation, and tissue mechanical function; (5) bioreactor design criteria that aim to enhance cell survival and the regeneration of functional 3D tissue constructs; (6) construct design criteria that aim to meet the metabolic and mechanical demands of specific tissue-engineering applications; and (7) improved understanding of biological and mechanical responses of an engineered tissue construct following implantation.

In this chapter, we focus on how *in vitro* culture parameters, including convective mixing, perfusion, culture duration, and mechanical conditioning (i.e., compression, tensile stretch, pressure, and shear), can affect the development and functional properties of engineered tissues. We further focus on engineered cartilage and cardiac tissues, although the concepts discussed are also of relevance to other tissues and organs that serve some mechanical function (e.g., muscle, tendon, ligament, bone, blood vessels, heart valves, bladder) and are the targets of tissue-engineering research efforts.

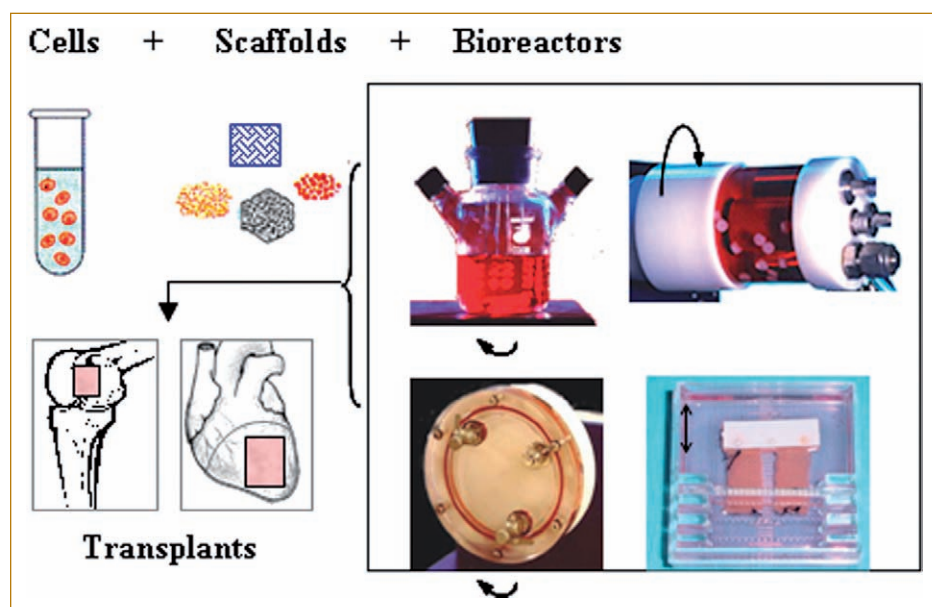

## II. KEY CONCEPTS

One approach to tissue engineering involves the *in vitro* culture of cells on biomaterial scaffolds to generate functional engineered tissues for *in vivo* applications, such as the repair of damaged articular cartilage or myocardium (Fig. 11.1). The **working hypothesis** is that *in vitro* culture

parameters determine the structural and mechanical properties of engineered tissues and, therefore, can be exploited to manipulate the growth and functionality of engineered tissues. ***In vitro culture parameters*** refer to tissue-engineering bioreactors, scaffolds, and mechanical conditioning that can mediate cell behavior and functional tissue assembly (Freed *et al.*, 2006).

**Bioreactors** are defined as *in vitro* culture systems designed to perform some or all of the following functions: (1) provide control over the initial cell distribution on 3D scaffolds; (2) provide efficient mass transfer of gases, nutrients, and regulatory factors to tissue-engineered constructs during their *in vitro* cultivation; and (3) expose the developing constructs to convective mixing, perfusion, and/or mechanical conditioning. Tissue-engineering bioreactors are also discussed in Chapter 12 and were reviewed in Darling and Athanasiou (2003), I. Martin *et al.* (2004), and Martin and Vermette (2005). **Scaffolds** are defined as 3D porous solid biomaterials designed to perform some or all of the following functions: (1) promote cell–biomaterial interactions, cell adhesion, and extracellular matrix (ECM) deposition; (2) permit sufficient transport of gases, nutrients, and regulatory factors to allow cell survival, proliferation, and differentiation; (3) biodegrade at a controllable rate that approximates the rate of tissue regeneration under the culture conditions of interest; and (4) provoke a minimal degree of inflammation or toxicity *in vivo*. Tissue-engineering scaffolds are also discussed in Chapters 19, 20, and 22–25 and were reviewed in Langer and Tirrell (2004), Muschler *et al.* (2004), Hollister (2005), and Lutolf and Aebell (2005).

The biological and mechanical requirements of an engineered tissue depend on the specific application (i.e., engineered cartilage should provide a low-friction, articulating

**FIG. 11.1.** Model system. Cells are cultured on porous solid biomaterial scaffolds in representative bioreactors (clockwise from the upper left image are shown the spinner flask, slow-turning lateral vessel, high-aspect-ratio vessel, and Bio-stretch®). Functional engineered cartilage or cardiac tissue can potentially be used to repair damaged articular cartilage or myocardium.

surface and be able to withstand and transmit loading in compression, tension, and shear, whereas engineered cardiac tissue should propagate electrical signals, contract in a coordinated manner, and withstand dynamic changes in pressure, tension, and shear). Tissue-specific requirements translate to design principles for functional tissue engineering as follows: (1) At the time of implantation, an engineered tissue should possess sufficient size and mechanical integrity to allow for handling and permit survival under physiological conditions; (2) Once implanted, an engineered tissue should provide some minimal level of biomechanical function immediately postimplantation that should improve progressively until normal tissue function has been restored; and (3) Once implanted, an engineered tissue should mature and integrate with surrounding host tissues.

One of the key challenges in realizing the approach shown in Fig. 11.1 is to optimize the *in vitro* culture environment in order to achieve the best possible conditions for functional tissue engineering. In particular, the ability precisely to define and control *in vitro* culture parameters, such as mass transport and biophysical signaling, can potentially be exploited to improve and ultimately control the structure, composition, and functional properties of engineered tissues. The following sections of this chapter consider *in vitro* studies aimed at clinical translation; representative *in vitro* culture environments; and the effects of convective mixing, perfusion, culture duration, and mechanical conditioning on engineered tissue constructs. Illustrative examples and alternative approaches for engineering cartilage and cardiac tissue are provided.

### III. *IN VITRO* STUDIES AIMED AT CLINICAL TRANSLATION

Osteochondral-defect repair remains an important, unsolved clinical problem, and a number of tissue-engineering approaches have been attempted to promote the functional integration of an engineered cartilage implant with adjacent host tissues (Hunziker, 1999, 2001). For example, we implanted composites based on engineered cartilage into defects in adult rabbit knees and found that the six-month repair cartilage exhibited physiologic thickness and Young's modulus but integrated in a variable and incomplete manner with adjacent host cartilage (Fig. 11.2 A–B) (Schaefer *et al.*, 2002, 2004). Further studies aimed at clinical translation are clearly needed, but *in vivo* models (e.g., orthotopic implants in animal knee joints) are complicated by high variability and biological and mechanical environments very different from those existing in human joint lesions (Hunziker, 1999, 2001). Moreover, further studies are needed to design appropriate physical rehabilitation protocols aimed at preventing overt failure, dislodgment, or fatigue of a tissue-engineered construct postimplantation. For example, a rehabilitation period consisting

of joint immobilization was shown to hinder the delamination of periosteal grafts in the goat knee (Driesang and Hunziker, 2000).

*In vitro* studies have been suggested to: (1) address the challenges of *in vivo* complexity in controllable model systems, and (2) define how an *in vitro*-grown construct may behave when implanted *in vivo* (Guilak *et al.*, 2001; Tognana *et al.*, 2005b). For example, we used rotating bioreactors and composites consisting of engineered cartilage discs within rings of native cartilage, vital bone, or devitalized bone to demonstrate significant effects of chondrogenic potential of the cells, degradation rate of the scaffold, developmental stage of the construct, and architecture of the adjacent tissue on construct development and integration (Obradovic *et al.*, 2001; Tognana *et al.*, 2005a, 2005b). Engineered cartilage constructs interfaced with the solid matrix of adjacent cartilage without any gaps or intervening capsule (Fig. 11.2C–D) and focal intermingling between construct collagen fibers and native cartilage collagen fibers provided evidence of structural integration (Fig. 11.2E). Interestingly, the composition and mechanical properties (e.g., adhesive strength, Fig. 11.2F) were superior for constructs cultured adjacent to bone as compared to cartilage and best for constructs cultured adjacent to devitalized bone. These findings could be rationalized by considering the differences in adjacent-tissue architecture (histological features) and transport properties (diffusivity) (Tognana *et al.*, 2005a). Consistently, perfused bioreactors were used to demonstrate significantly higher amounts of GAG and total collagen in engineered cartilage cocultured adjacent to engineered bone than to either engineered cartilage, native cartilage, or native bone (Mahmoudifar and Doran, 2005b).

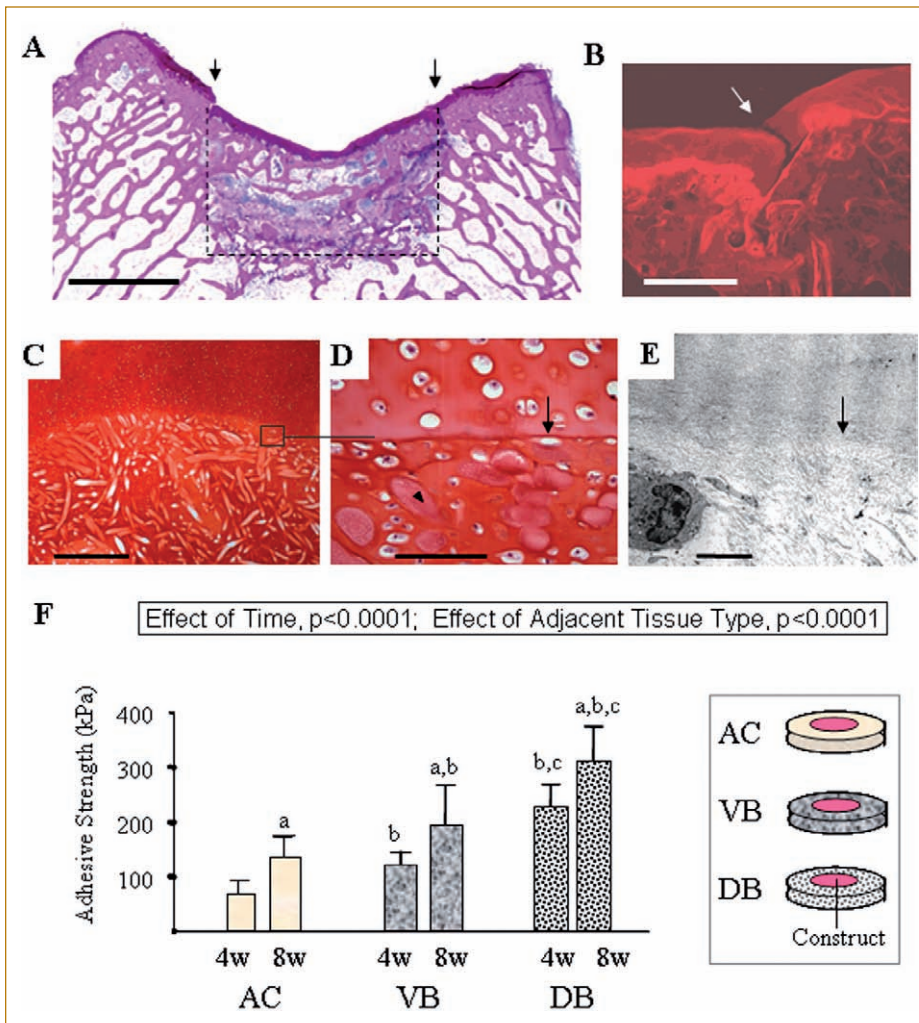

Hypothesis-driven experiments aimed at elucidating cell- and tissue-level responses to biological, hydrodynamic, and mechanical stimuli are expected to improve our understanding of complex *in vivo* phenomena and to promote clinical translation of tissue-engineering technologies. In this context, the *in vitro* culture environment plays a key role by allowing for reproducible test conditions, and tissue culture bioreactors represent a controllable model system for (1) studying the effects of biophysical stimuli on cells and developing tissues, (2) simulating responses of an *in vitro*-grown construct to *in vivo* implantation and thereby helping to define its potential for survival and functional integration, and (3) developing and testing physical therapy regimens for patients who have received engineered tissue implants.

### IV. REPRESENTATIVE *IN VITRO* CULTURE ENVIRONMENTS

#### Spinner Flasks

A spinner flask system (Table 11.1 column 1; Fig. 11.1, upper left image) has been developed for cell seeding of

**FIG. 11.2.** Studies of the clinically relevant problem of engineered cartilage integration. **(A–B)** Integration between an engineered cartilage implant and adjacent host cartilage was variable and incomplete (arrows) six months after osteochondral-defect repair in adult rabbit knee joints. **(A)** Alcian blue stain; scale bar: 2.5 mm; dashed line shows borders of original defect. **(B)** Immunofluorescence microscopy; scale bar: 400  $\mu\text{m}$ . **(C–F)** Engineered cartilage integration was studied by using rotating bioreactors to culture construct discs within rings of articular cartilage (AC), vital bone (VB), and devitalized bone (DB). **(C, D, E)** Histology of the construct–AC interface; arrows at interfaces point toward the construct; arrowheads indicate the scaffold. **(C and D)** Safranin-O stain; scale bars 500  $\mu\text{m}$  and 50  $\mu\text{m}$ , respectively. **(E)** TEM; scale bar 5  $\mu\text{m}$ . **(F)** Adhesive strength for construct discs cultured in rings of AC (open bars), VB (grey bars), or DB (stipled bars) for four or eight weeks (4 w, 8 w). a: significant difference due to time; b: significantly different from the corresponding AC composite; c: significantly different from the corresponding VB composite. **(A–B)** Reproduced with kind permission of the publisher from Schaefer *et al.* (2004). **(C–D)** Reproduced with kind permission of the publisher from Tognana *et al.* (2005b). **(E–F)** Reproduced with kind permission of the publisher from Tognana *et al.* (2005a).

3D scaffolds and cultivation of 3D tissue constructs (e.g., Freed and Vunjak-Novakovic, 1995, 1997; Freed *et al.*, 1998; Martin *et al.*, 1998, 2001; Vunjak-Novakovic *et al.*, 1998; Bursac *et al.*, 1999; Gooch *et al.*, 2001a, 2001b; Papadaki *et al.*, 2001; Pei *et al.*, 2002b; Schaefer *et al.*, 2002; Mahmoudifar *et al.*, 2005a, 2005b). In brief, spinner flasks are 12-cm-high  $\times$  6.5-cm-diameter vessels that provide gas exchange via side arms with loose screw caps and mixing via a nonsuspended  $4.5 \times 0.8$ -cm magnetic stir bar. Scaffolds are fixed on two to four needles placed symmetrically in a stopper in the mouth of the flask. Each needle holds up to three scaffolds separated by silicone spacers. The flask is filled with 100–120 mL of media, inoculated with cells, and then stirred at  $\sim 50$  rpm. Smaller spinner flasks with operating volumes of 60 mL can also be used.

### Rotating Bioreactors

Two rotating bioreactor systems were developed at NASA for *in vitro* tissue culture on earth: the slow-turning lateral vessel (STLV) (Table 11.1, column 2; Fig. 11.1, upper right image) and high-aspect-ratio vessel (HARV) (Table

11.1, column 3; Fig. 11.1, lower left image) (e.g., Schwarz *et al.*, 1992; Freed and Vunjak-Novakovic, 1995, 1997; Freed *et al.*, 1998; Riesle *et al.*, 1998; Unsworth and Lelkes, 1998; Carrier *et al.*, 1999; Vunjak-Novakovic *et al.*, 1999; Obradovic *et al.*, 2001; Madry *et al.*, 2002; Pei *et al.*, 2002a, 2002b; Bursac *et al.*, 2003; Yu *et al.*, 2004; Tognana *et al.*, 2005a, 2005b; Marolt *et al.*, 2006). Also, a rotating-wall perfused vessel (RWPV) was developed at NASA for tissue culture during spaceflight (Table 11.1, column 4) (Freed *et al.*, 1997; Jessup *et al.*, 2000; Freed and Vunjak-Novakovic, 2002).

In the STLV, tissues are housed in the annular space between two concentric cylinders (outer and inner diameters of 5.75 and 2 cm, respectively; 5 cm high), whereas the HARV is a discoid vessel (10 cm in diameter, 1.3 cm high). In the STLV and HARV, gas exchange is provided by an internal, fiber-reinforced, 175- $\mu\text{m}$ -thick silicone membrane. A smaller STLV and HARV, with operating volumes of 50–60 mL, are also available. The STLV or HARV is completely filled with medium and then rotated around its central axis. Rotation suspends the constructs within the

culture medium due to the combined effects of gravitational (weight and buoyancy) and flow-induced (drag) forces (Freed and Vunjak-Novakovic, 1995). The rotation rate is adjusted as needed (e.g., 10–40 rpm) to maintain the constructs freely suspended within the vessel during *in vitro* culture.

In the RWPV, tissues are housed in the annular space between two concentric cylinders (outer and inner diameters of 5 and 1.5 cm, respectively; 6.3 cm high). In the micro-gravity environment of space, where gravitational settling of constructs does not occur, convective mixing is provided by a flat disc (3.8 cm in diameter) that is attached to one end of the inner cylinder and serves as a centrifugal pump and by differential rotation of the inner and outer cylinders (e.g., at 10 and 1 rpm) (Begley *et al.*, 2000). In the RWPV system, culture medium is periodically circulated through the vessel via an inlet at one end of the annulus and a spin-filter outlet at its inner cylinder, and gas exchange is provided by an external, fiber-reinforced, 175- $\mu$ m-thick silicone membrane (Freed and *et al.*, 1997; Jessup *et al.*, 2000; Freed and Vunjak-Novakovic, 2002).

### Mechanical Conditioning

A variety of devices have been custom designed and built to study effects of mechanical conditioning (i.e., compression, tension, pressure, or shear) on cells and tissues *in vitro* (reviewed in Brown, 2000; Darling and Athanasiou, 2003). For engineering cartilage, devices typically apply dynamic compression (e.g., Buschmann *et al.*, 1995; Mauck *et al.*, 2000), hydrostatic pressure (e.g., Mizuno *et al.*, 2002; Toyoda *et al.*, 2003), or mechanical shear (Waldman *et al.*, 2003). For engineering muscular and cardiovascular tissues, devices typically apply dynamic tensile strain (Vandenburgh and Karlisch, 1989; Vandenburgh *et al.*, 1991; Kim *et al.*, 1999; Niklason *et al.*, 1999; Fink *et al.*, 2000; Sodian *et al.*, 2001; Akhyari *et al.*, 2002; Powell *et al.*, 2002; Zimmermann *et al.*, 2002; Gonen-Wadmany *et al.*, 2004; Boublik *et al.*, 2005) or pulsatile hydrostatic pressure (Niklason *et al.*, 1999; Sodian *et al.*, 2001). In one representative example (Fig. 11.1, lower right image), a commercially available electromagnetic device (Biostretch®, ICCT, Ontario, Canada) (Liu *et al.*, 1999) was used to study effects of cyclic stretch on engineered cardiac constructs (Boublik *et al.*, 2005).

## V. CONVECTIVE MIXING, FLOW, AND MASS TRANSFER

### Cell Seeding of 3D Scaffolds

Cell seeding of a biomaterial scaffold is the first step in tissue engineering and plays a critical role in determining subsequent tissue formation (Freed *et al.*, 1994a; Kim *et al.*, 1998). We showed that high and spatially uniform initial cell densities were associated with increases in extracellular matrix (ECM) deposition and compressive modulus in engineered cartilage (Vunjak-Novakovic *et al.*, 1996, 1999; Freed

*et al.*, 1998) and with increases in contractile proteins and contractility in engineered cardiac tissue (Carrier *et al.*, 2002a; Radisic *et al.*, 2003). For example, the spinner flask system (Table 11.1, Fig. 11.1) improved the efficiency and spatial uniformity of cell seeding throughout porous solid 3D scaffolds (e.g., fiber-based textiles and porogen-leached sponges) as compared with controls seeded statically (Vunjak-Novakovic *et al.*, 1996, 1998). The probable mechanism of cell seeding in the spinner flask system is convection of suspended cells into the porous scaffold leading to inertial impacts between cells and scaffold and then to cell adhesion. However, cell seeding in spinner flasks is not perfectly uniform, and initial cell densities are highest at the construct surfaces (Freed *et al.*, 1998; Mahmoudifar and Doran, 2005a). Moreover, for cardiac tissue engineering, the cell seeding efficiency in spinner flasks is only ~60% (Carrier *et al.*, 1999).

Alternative systems for cell seeding of 3D scaffold systems are based on convective flow of a cell suspension directly through a porous solid 3D scaffold via filtration (Li *et al.*, 2001) or bi-directional perfusion (Radisic *et al.*, 2003; Wendt *et al.*, 2003). Engineered cartilage seeded in perfused bioreactors with alternating medium flow reportedly exhibited higher cell viability and uniformity than controls seeded statically and in spinner flasks (Wendt *et al.*, 2003). Likewise, engineered cardiac tissue seeded in perfused bioreactors with alternating medium flow exhibited higher cell viability and spatial uniformity than controls seeded in mixed petri dishes (Radisic *et al.*, 2003).

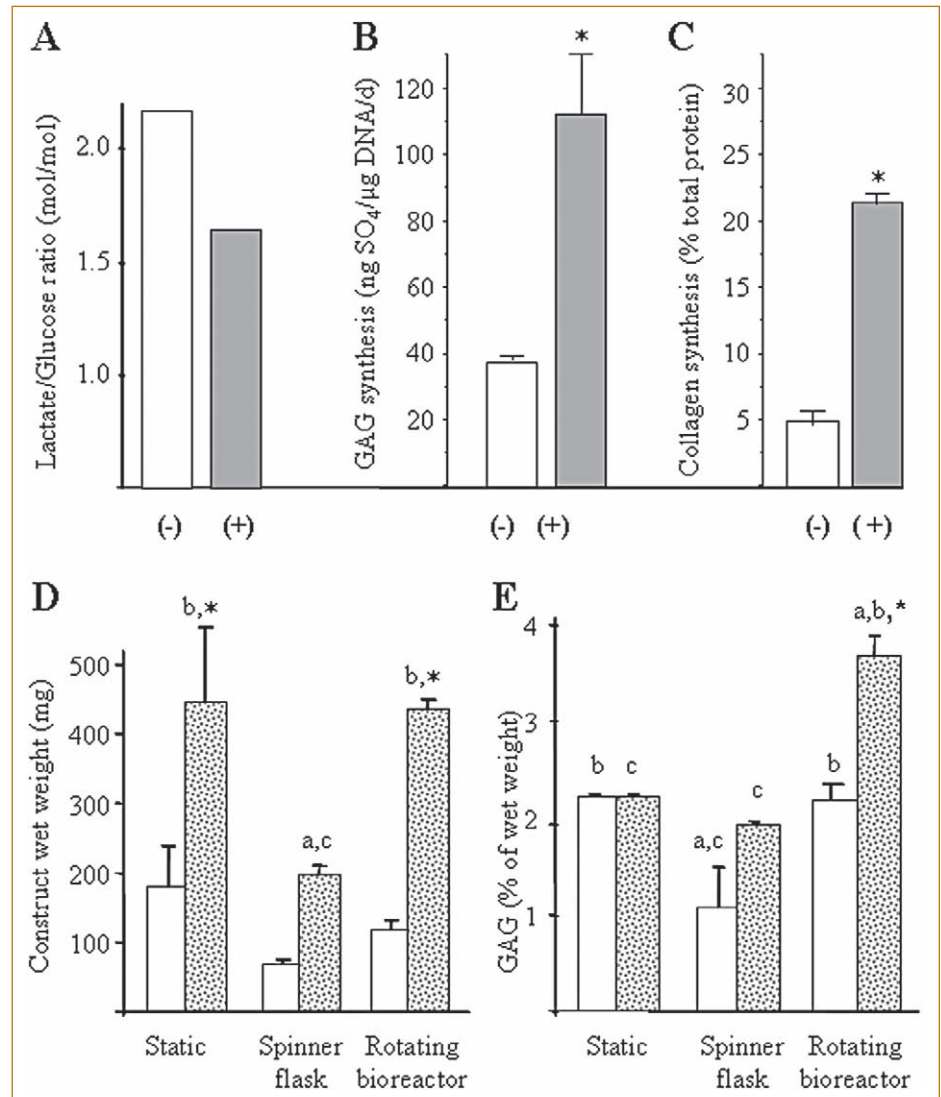

### Cultivation of 3D Tissue Constructs

Convective mixing, flow, and mass transport are required to supply the oxygen, nutrients, and regulatory factors that are in turn required for the *in vitro* cultivation of large tissue constructs (Karande *et al.*, 2004; Muschler *et al.*, 2004; Martin and Vermette, 2005). Oxygen is the factor that generally limits cell survival and tissue growth, due to its relatively low stability slow diffusion rate and high consumption rate (Martin and Vermette, 2005). Different tissue types have different mass transport requirements, depending on cell type(s), concentrations, and metabolic activities. For example, articular cartilage, an avascular tissue, has a lower requirement for oxygen than myocardium, a highly vascularized tissue. Convective mixing of the culture media in rotating bioreactors supported the growth of engineered cartilage constructs 5–8 mm thick (Freed *et al.*, 1997, 1998; Vunjak-Novakovic *et al.*, 1999). Chondrocyte metabolic function was in between aerobic and anaerobic (assessed by a ratio of lactate produced to glucose consumed, L/G ~ 1.5), and synthesis rates of glycosaminoglycans (GAG) and collagen were high in rotating bioreactors with gas exchange membranes, whereas anaerobic metabolism (L/G ~ 2.0) and significantly lower ECM synthesis rates were measured in control bioreactors without gas exchange membranes (Fig. 11.3A–C) (Obradovic *et al.*, 1999). In the

case of engineered cardiac tissue, convective mixing in rotating bioreactors and spinner flasks supported the growth of a tissue-like surface layer  $\sim 100\ \mu\text{m}$  thick (Carrier *et al.*, 1999, 2002b; Papadaki *et al.*, 2001). However, convective flow of culture medium directly through an engineered cardiac construct within a perfused bioreactor can significantly improve its thickness and spatial homogeneity (Carrier *et al.*, 2002a; Radisic *et al.*, 2003, 2004b, 2006) (also see Chapter 38). Experimental and modeling studies have correlated oxygen gradients within engineered tissues with morphology and composition (Obradovic *et al.*, 2000; Malda *et al.*, 2003, 2004; Martin and Vermette, 2005).

Regulatory factors can be used as culture medium supplements to selectively induce chondrogenic or osteogenic differentiation of progenitor cells harvested from the bone marrow (e.g., Martin *et al.*, 2001; Muschler *et al.*, 2004; Marott *et al.*, 2006) and to enhance the growth, composition, and mechanical function of engineered cartilage based on

chondrocytes (Gooch *et al.*, 2001a; Pei *et al.*, 2002a; Mauck *et al.*, 2003). In one study of engineered cartilage cultured in medium that was supplemented, or not, with insulin-like growth factor (IGF-I) using three different culture environments (rotating bioreactors, spinner flasks, and static), the growth and hydrodynamic factors (1) independently modulated construct structure, composition, and mechanical properties and (2) in combination produced effects superior to those that could be obtained by modifying the factors individually (Gooch *et al.*, 2001a). In particular, construct size was increased by IGF-I in all culture environments (Fig. 11.3D), whereas the fractional amount of GAG was significantly increased only if IGF-I was used in combination with rotating bioreactors (Fig. 11.3E). Consistently, others have demonstrated synergistic effects of growth factors and dynamic mechanical loading on the structure, composition, and mechanical function of engineered cartilage constructs (Mauck *et al.*, 2003).

**FIG. 11.3.** Convective flow and mass transport affect cell function and the size and composition. **(A–C)** Engineered cartilage cultured for five weeks in rotating bioreactors with (+) or without (–) a gas exchange membrane. **(A)** Cell metabolism (ratio of lactate to glucose); **(B and C)** bio-synthesis rates or GAG (normalized per cell) and collagen (as a percentage of the total protein). \*: Significant effect of gas exchange. **(D–E)** Engineered cartilage constructs cultured for four weeks in a static flask, spinner flask, or rotating bioreactor, using basal media (white bars) or media supplemented, with insulin-like growth factor (IGF-I, 100 ng/mL, stipled bars). **(D and E)** Construct wet weight (mg) and GAG (% of wet weight). a: Significantly different from static flask; b: Significantly different from spinner flask; c: Significantly different from rotating bioreactor; \*: Significantly different from basal media. **(A–C)** Data from Obradovic *et al.* (1999). **(D–E)** Reproduced with kind permission of the publisher from Gooch *et al.* (2001).

Hydrodynamic forces associated with convective mixing affect the morphology of tissue-engineered cartilage. For example, engineered cartilage cultured in rotating bioreactors had thinner surface capsules and higher fractional amounts of GAG than constructs grown in spinner flasks (Freed and Vunjak-Novakovic, 1995, 1997; Vunjak-Novakovic *et al.*, 1999; Martin *et al.*, 2000). Moreover, engineered cartilage constructs cultured in rotating bioreactors in normal gravity (on earth) tended to maintain their initial discoid shape, whereas constructs cultured in microgravity (aboard the Mir space station) tended to become spherical, and constructs cultured in normal gravity had higher GAG contents and compressive moduli than constructs cultured in microgravity (Freed *et al.*, 1997). Importantly, different flow fields were utilized in normal gravity and in microgravity, in order to ensure mass transfer in the two environments; i.e., on earth convective mixing was achieved by gravitational settling of constructs that were freely suspended by synchronous rotation of the inner and outer cylinders at 28 rpm, whereas aboard Mir convective mixing was induced by differential rotation of the inner and outer cylinders at 10 and 1 rpm, respectively. Therefore, on earth gravitational settling of initially discoid constructs tended to align their flat circular areas perpendicular to the direction of motion, increasing shear and mass transfer circumferentially and promoting preferential growth in the radial direction, whereas on Mir exposure of constructs to uniform shear and mass transfer at all surfaces promoted equal tissue growth in all directions such that constructs tended to become spherical.

The effects of hydrodynamic forces on construct morphology were further investigated by the techniques of particle-image velocimetry (Brown, 1998; Neitzel *et al.*, 1998) and computational modeling (Neitzel *et al.*, 1998; Lappa, 2003; Sucosky *et al.*, 2004). The flow field in the spinner flask was unsteady, turbulent (Reynolds number of 1758), and characterized by large spatial variations in the velocity field and maximum shear stresses (Fig. 11.4A) (Sucosky *et al.*, 2004). In contrast, the flow field in the rotating bioreactor (STLV) was predominately laminar (Brown, 1998), with shear stresses of  $\sim 1$  dyn/cm<sup>2</sup> (Freed and Vunjak-Novakovic, 1995; Neitzel *et al.*, 1998) and a well-mixed interior due to secondary flow patterns induced by the freely settling constructs (Fig. 11.4B and C, which show, respectively, flow-visualization and velocity-vector fields). A model of tissue growth in the rotating bioreactor, which accounted for the intensity of convection over six weeks of *in vitro* culture, was used to predict the morphological evolution of an engineered cartilage construct (Lappa, 2003). In particular, the model predicted that high shear and mass transfer at the lower corners of a settling, discoid construct would preferentially induce tissue growth in these regions and that temporal changes in construct size and shape would further enhance local variations in the flow field in a manner that

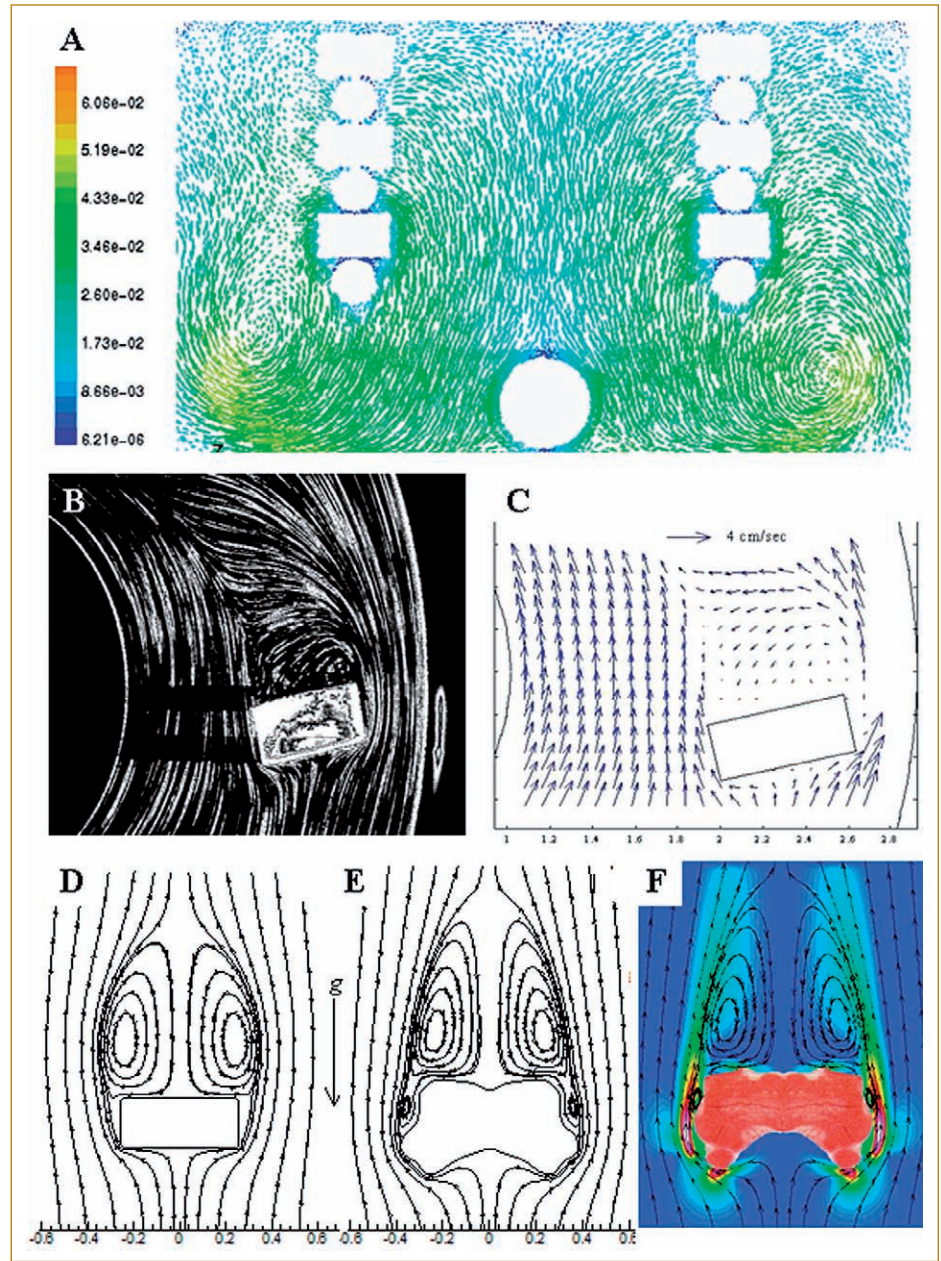

accentuated localized tissue growth (Fig. 11.4D–F). The computed velocity fields and shear stress data corresponded well with the morphological evolution of engineered cartilage, as shown by superimposing a calculated flow field on a histological cross section of an actual 42-day construct (Fig. 11.4F). The foregoing examples suggest that combining experimental studies and modeling of hydrodynamic shear stresses and concentration gradients in bioreactors may be exploited to derive underlying mechanisms and potentially control the growth of engineered tissue constructs.

Alternative systems for cultivation of 3D tissue constructs are based on the convective flow of the culture medium directly through a porous construct via multipass perfusion. In particular, a single construct is placed within a bioreactor such that there is a tight fit between the circumference of the construct and the inner wall of the bioreactor, and then a pump is used to provide the flow of culture medium directly through the construct. Perfusion enhances mass transfer and generates compressive and shear forces, the magnitude of which can be controlled by varying the fluid flow rate. In the case of engineered cartilage, constructs cultured in perfused bioreactors contained higher amounts of ECM as compared with static controls (Dunkelman *et al.*, 1995; Pazzano *et al.*, 2000; Davisson *et al.*, 2002b). Furthermore, periodic reversal of flow direction enhanced construct size and amounts of cartilaginous ECM as compared with unidirectional flow (Mahmoudifar and Doran, 2005a). In the case of engineered cardiac tissue, constructs cultured in perfused bioreactors exhibited enhanced cell survival and contractile function as compared with nonperfused controls (Carrier *et al.*, 2002a, 2002b; Radisic *et al.*, 2003, 2004b, 2006) (also see Chapter 38).

### Integrated Systems for Cell Seeding and Tissue Cultivation

We showed advantages of using spinner flasks for cell seeding and then rotating bioreactors for long-term cultivation of engineered tissue constructs in a systematic study involving two different scaffold materials (benzylated hyaluronan, Hyaff-11<sup>®</sup> (Fidia Advanced Biopolymers) and polyglycolic acid, PGA) and three different scaffold structures (porogen-leached sponge and nonwoven and woven textiles) (Pei *et al.*, 2002b). The culture system was the parameter with the highest impact on the size, composition, and mechanical properties of three-day and four-week constructs (Fig. 11.5, Table 11.2). Importantly, findings attributed to the culture system represented the integrated effects of cell seeding and tissue culture. The three-day constructs seeded in spinner flasks had higher numbers of more uniformly distributed cells than statically seeded controls, and the four-week constructs cultured in bioreactors were larger and thicker and had higher amounts of cartilaginous ECM than controls seeded and cultured in petri dishes (Fig. 11.5, Table 11.2). Bioreactor-grown constructs had compressive

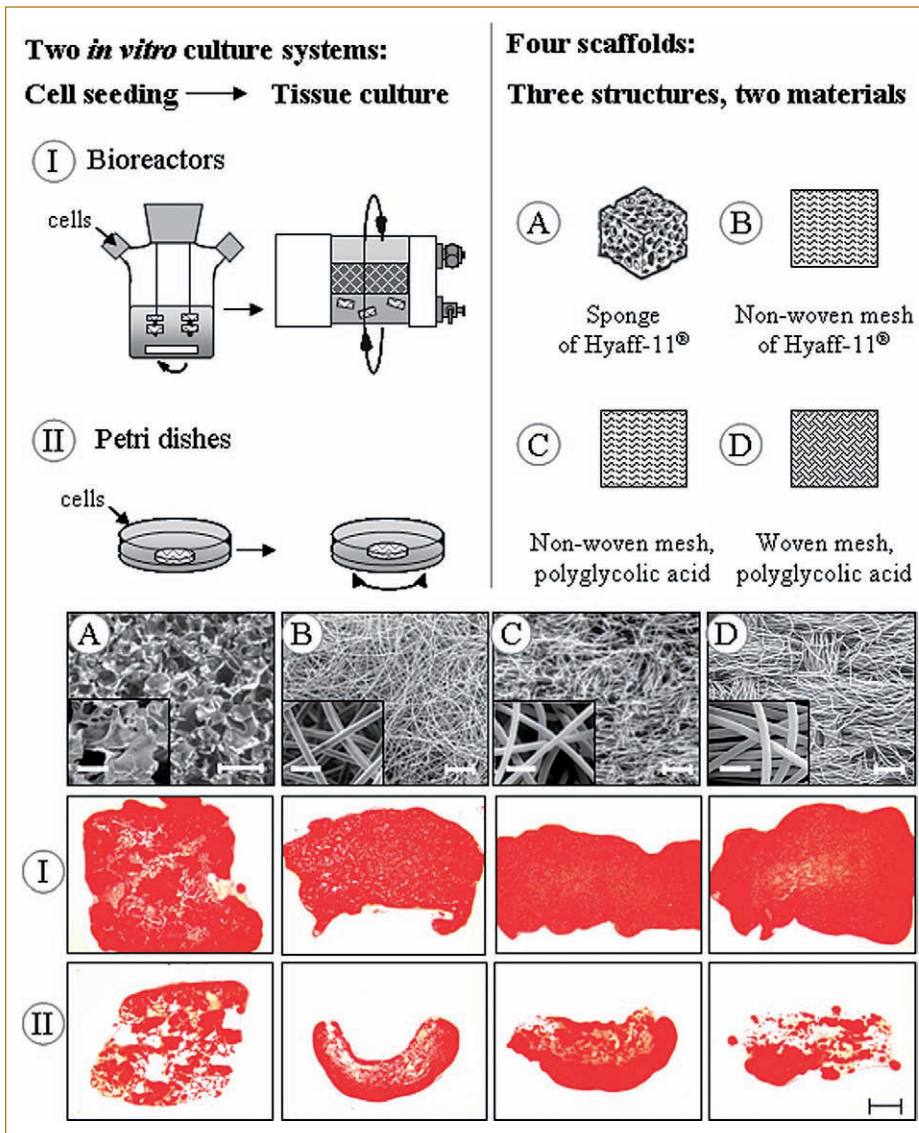

**FIG. 11.4.** Convective mixing and mass transfer in bioreactors; effects on construct morphology. Flow patterns in **(A)** a spinner flask containing two needles, each with three constructs and three spacers, and a nonsuspended stir bar and **(B–F)** a rotating vessel containing one construct. Flow-visualization **(B)** and velocity-vector **(C)** fields (the latter obtained by particle-image velocimetry) corresponded well with computed velocity fields on culture day 0 **(D)** and day 40 **(E–F)**. Computed velocity fields and shear stress data also corresponded well with the morphology of an actual cartilage construct (calculations and histological cross section of a 42-day construct are superimposed **F**). **(A)** Reproduced with kind permission of the publisher from Sucosky *et al.* (2004). **(B, C)** Reproduced with kind permission of Academic Press, *Principles of Tissue Engineering*, 2000 (Lanza *et al.*, eds.), Fig. 13.4, p. 148. **(D–F)** Reproduced with kind permission of the publisher from Lappa (2003).

moduli in the range of native articular cartilage (0.13–0.54 MPa, Table 11.2), whereas mechanical properties of controls cultured in petri dishes could not be properly measured due to their poor structural integrity and spatial inhomogeneity. In an alternative approach, an integrated bioreactor system was custom built to provide rotational flow during cell seeding and then perfusion during construct cultivation (Sodian *et al.*, 2002). One advantage this approach may offer over the use of different bioreactors for cell seeding and long-term tissue cultivation is a lower risk of contamination.

## VI. CULTURE DURATION AND MECHANICAL CONDITIONING

### Effects of Culture Duration

With increasing time of *in vitro* culture, chondrocytes assemble a mechanically functional ECM (e.g., Buschmann *et al.*, 1995) and cardiomyocytes develop contractile responsiveness to electrical impulses (e.g., Radisic *et al.*, 2004a). For example, primary bovine calf chondrocytes seeded on nonwoven PGA mesh in spinner flasks and then cultured in rotating bioreactors synthesized (Fig. 11.6A) and deposited

**FIG. 11.5.** Culture system and scaffold structure individually and interactively affect construct morphology. Two culture systems were used to study four different scaffolds. In culture system I, cells were seeded in spinner flasks and constructs were cultured for four weeks in rotating bioreactors. In culture system II, cells were seeded statically and constructs were cultured for four weeks in mixed petri dishes. (A–D) Schematics and SEM of the scaffolds. Scale bars: 500  $\mu\text{m}$ ; insets: 50  $\mu\text{m}$ . (I, II) Histological cross sections of four-week constructs made with scaffolds (A–D) in culture systems I and II. (Fig. 11.6B) a cartilaginous ECM consisting of GAG and collagen type II (Freed *et al.*, 1998). Importantly, the relatively high rates of ECM synthesis and deposition by the calf chondrocytes matched approximately the relatively high degradation rate of the PGA scaffold (Fig. 11.6B), a finding that did not hold true when the same scaffold was studied with other cell types (e.g., bone marrow stromal cells (Martin *et al.*, 1999)) or in other culture environments (e.g., mixed petri dishes (Freed *et al.*, 1994b)).

The structural and functional properties of tissue-engineered constructs can be improved to some degree by extending the duration of *in vitro* culture. For example, seven-month-long cultures carried out in rotating bioreactors operated on earth yielded engineered cartilage constructs with very high GAG fractions ( $\sim 8\%$  of wet weight) and compressive moduli ( $\sim 0.9$  MPa) that were comparable to normal articular cartilage (Fig. 11.6C–D), although the col-

lagen fraction and dynamic stiffness of the seven-month constructs remained subnormal (Freed *et al.*, 1997). Also, the adhesive strength of engineered cartilage to adjacent cartilage and bone improved between four and eight weeks of culture (Fig. 11.2F). Engineered cardiac tissue cultured for up to eight days exhibited a temporal increase in contractile amplitude (Radisic *et al.*, 2004a), but at present the maximal contractile force generation reported for an engineered cardiac construct ( $\sim 4$  mN/mm<sup>2</sup>) remains more than an order of magnitude below that of normal heart muscle (Eschenhagen and Zimmermann, 2005).

### Effects of Mechanical Conditioning

It is well known that mechanical forces play a key role in determining the architecture of native tissues such as bone (Thompson, 1977), and a wide variety of laboratory devices have been developed for mechanical conditioning

of cell and tissue cultures (reviewed in Brown, 2000). There is growing evidence that mechanical factors can play an important role in determining stem cell fate (Estes *et al.*, 2004). In particular, the role of *in vitro* mechanical stress in maintaining and promoting the chondrogenic phenotype has been the topic of several recent investigations, but the specific influences of different physical stimuli and their interactions with the biochemical environment are not fully understood. For example, dynamic compression caused an approximately two-fold increase in cartilage nodule density and a 2.5-fold increase in GAG synthesis in stage 23/24 chick limb-bud cells cultured in agarose gel (Elder *et al.*, 2000). Likewise, cyclic hydrostatic pressure significantly increased the amounts of proteoglycan and collagen in aggregates of human bone marrow stromal cells (Angele *et al.*, 2003). In another study, compression enhanced chondrogenic differentiation in mouse embryonic E10 stage cells embedded in collagen type I as compared to unloaded controls, as shown by up-regulating SOX-9 and down-regulating IL-1 $\beta$  expression (Takahashi *et al.*, 1998).

In the case of engineered cartilage, a number of studies have shown that mechanical conditioning can enhance chondrogenesis. Dynamic loading can increase GAG accumulation and ECM assembly and, hence improve the mechanical properties of constructs based on bovine calf articular chondrocytes and a variety of 3D scaffolds, including agarose gel (Buschmann *et al.*, 1995; Mauck *et al.*, 2000, 2002), PGA nonwoven mesh (Davisson *et al.*, 2002a), and

self-assembling peptide gel (Kisiday *et al.*, 2004). The response of chondrocytes to dynamic loading depended on the amount and composition of ECM in the developing construct (Demarteau *et al.*, 2003), and in some studies loading increased both synthesis of new GAG and its loss into the culture media (Kisiday *et al.*, 2004; Seidel *et al.*, 2004). Dynamic loading also increased the amount of ECM and the compressive modulus of engineered cartilage based on calf chondrocytes and a porous calcium polyphosphate scaffold, and, interestingly, application of shear stress yielded constructs with higher amounts of ECM and higher compressive moduli than compressive stress (Waldman *et al.*, 2003). Likewise, application of dynamic hydrostatic pressure affected chondrogenesis in 3D cultures of bovine (Mizuno *et al.*, 2002) and human (Toyoda *et al.*, 2003) chondrocytes.

In the case of engineered muscle (skeletal, smooth, and cardiac), dynamic tensile and pulsatile loading can affect construct composition, contractility, and pharmacological responsiveness (Vandemburgh *et al.*, 1991; Kim *et al.*, 1999; Niklason *et al.*, 1999; Fink *et al.*, 2000; Sodian *et al.*, 2001; Akhyari *et al.*, 2002; Powell *et al.*, 2002; Zimmermann *et al.*, 2002; Gonen-Wadmany *et al.*, 2004; Boublik *et al.*, 2005). In one representative study, cyclic stretch (applied continuously for a one-week period at a frequency of 1 Hz and strain amplitudes ranging from 1% to 10%) affected the composition and mechanical properties of engineered cardiac constructs based on a knitted, elastomeric fabric

**FIG. 11.7.** Effects of culture duration and cyclic stretch on the composition and function of engineered cardiac tissue. **(A)** DNA content, **(B)** collagen content, **(C)** tensile stiffness, and **(D)** ultimate tensile strength (UTS) of constructs based on cardiomyocytes cultured for two hours (2 h) or one week (1 w) without (Ctl.) or with cyclic stretch (Str.) applied at different strain amplitudes (1%, 3.5%, and 7%). The knitted elastomeric scaffold and the fibrin hydrogel are respectively denoted by (Knit) and (Fn) respectively. a: Significant effect of culture time; \*: Significant effect of cyclic stretch. Reproduced with kind permission of the publisher from Boublik *et al.* (2005).

(Hyalonect<sup>®</sup>, Fidia Advanced Biopolymers), fibrin gel, and cardiomyocytes (Fig. 11.7) (Boublik *et al.*, 2005). As compared with unstretched controls, dynamic stretch increased construct amounts of DNA and collagen in a manner that depended on strain amplitude (Fig. 11.7A–B), did not affect tensile stiffness (Fig. 11.7C), and decreased ultimate tensile strength (Fig. 11.7D). Likewise, in engineered cardiac constructs based on vascular cells and poly-4-hydroxybutyrate scaffolds, pulsatile stimulation enhanced construct amounts of DNA and collagen but did not affect mechanical properties (Yang *et al.*, 2006). Notably, in the two aforementioned studies, construct biomechanical properties were determined mainly by the scaffold. In contrast, for engineered cardiac tissues based on collagen scaffolds, construct biomechanical properties were cell and ECM derived, and cyclic stretch not only affected construct structure (e.g., orientation of cells and collagen) (Gonen-Wadmany *et al.*, 2004) but also enhanced mechanical function (i.e., contractility) (Fink *et al.*, 2000; Akhyari *et al.*, 2002;

Zimmermann *et al.*, 2002). Together, mechanical-conditioning studies demonstrate that specific loading protocols may be exploited to stimulate specific responses in engineered tissue constructs and emphasize the potential utility of bioreactors in studying and promoting *ex vivo* construct formation.

## VII. CONCLUSIONS

As the field of tissue engineering progresses, it is becoming apparent that the next generation of functional tissue replacements may require additional exogenous influences to achieve many of the important requirements for long-term success. Two such needs — physiologic mechanical properties and the ability to grow and remodel in a manner that allows for restoration of physiologic functions — can potentially be achieved by the judicious selection of *in vitro* culture parameters. For example, scaffolds can provide tissue-mimetic mechanical properties (Moutos *et al.*, 2007), and bioreactors can be exploited to enhance *in vitro*

generation of 3D engineered tissue constructs and to test their physiologic responses in environments mimicking those in which they will eventually be implanted (Freed *et al.*, 2006). In this chapter, we provided representative studies of tissue engineered cartilage and cardiac constructs in which *in vitro* culture parameters were manipulated to accelerate the development and integration of 3D engineered tissue constructs and to improve their biomechanical

properties. Effects of *in vitro* convective flow (i.e., flow regimen and associated mixing, mass transfer and shear) and mechanical conditioning (i.e., compression, tensile stretch, pressure and shear) were discussed. Given the rapid evolution of the field of functional tissue engineering, it is important to consider *in vitro* culture parameters in conjunction with novel growth factors, biomaterials, gene therapies, and other emerging technologies.

## VIII. ACKNOWLEDGMENTS

We would like to thank J. Boublik, J. Brown, R. Carrier, B. Estes, J. Gimble, K. Gooch, M. Lappa, I. Martin, F. Moutos, B. Obradovic, M. Pei, D. Schaefer, L. Setton, P. Sucusky, E. Tognana, and G. Vunjak-Novakovic for contributing to the studies described in this chapter; R. Langer, M. Moretti, and

G. P. Neitzel for advice and critical reviews; and S. Kangiser for help with manuscript preparation. This work was supported by National Aeronautics and Space Administration Grant NNJ04HC72G and National Institutes of Health Grants AR49294, AG15768, AR50245, and AR48182.

### I. INTRODUCTION

In this chapter, we review the principles of cell culture and bioreactor design in the context of tissue engineering. In the first part, we describe the principles of cell and tissue culture, with emphasis on the initiation of culture, transformation, preservation, and validation of the cells and differentiation methods that utilize simple and well-established petri dish protocols. In the second part, we describe the design and operation of tissue engineering bioreactors, with focus on mass transport considerations associated with environmental control, and the provision of biophysical signals associated with the modulation of cell differentiation and functional tissue assembly. We provide eight examples of representative bioreactor designs that illustrate how some of the differentiation factors are provided in a physiologically relevant fashion.

### II. BASIC PRINCIPLES OF CELL AND TISSUE CULTURE

Historically, tissue culture arose from the concept that small fragments of tissue could somehow be maintained outside of the body in an appropriate environment such that the tissue cells survived. Harrison (1907) was the first to show that not only could cells survive but that they could perform functions, in his case neurite outgrowth, compara-

ble to their normal *in vivo* activity. Some years later, tissue culture diverged into *cell culture*, where survival and propagation of the cells was paramount, and *organ culture*, where the retention of histological structure was seen as the major endpoint and indicative of the retention of *in vivo* function, so clearly lost in dispersed cell culture.

Cell culture has the advantage that it is more quantifiable and allows the development of optimized culture conditions, initially for cell proliferation but ultimately for functional expression as well. However, it was clear from early work that functional expression depended heavily on cell-cell interaction, both *homotypic* (among cells of the same lineage) and *heterotypic* (among cells of different lineages), and on the interaction of the cells with the extracellular matrix, itself a product of the interacting cells. For many years this was achievable only via organ culture. But recent advances in organotypic culture, including filter well inserts and engineered tissue constructs, mean that controlled characterized cell populations can be recombined and the nature of specific interactions defined. In some cases, e.g., with skin, it is possible to create a construct that allows complete terminal differentiation of keratinized squames by providing the correct cellular interactions, matrix, and oxygen tension (Maas-Szabowski *et al.*, 2002).

As a resource, cell culture has contributed historically not just to fundamental mechanistic studies of genotypic

**Table 12.1.** Selective pressure during isolation and culture

Stage	Process	Selection
<b>Primary culture</b>	Explant	Survival <i>in vitro</i>
	Trypsin digestion	Adhesion; cell migration into outgrowth
	Collagenase digestion	Cells resistant to trypsin
	Mechanical disaggregation	Epithelial or endothelial cell clusters
<b>Subculture</b>		Cells resistant to mechanical damage; eliminates fragile cells
	Explant transfer	Resistance to trypsin; ability to reattach; proliferation
	Trypsinization	Slowly migrating cells, e.g., epithelium
	Scraping	Cells resistant to trypsin
	Dispase	Cells resistant to mechanical damage
	Selective agents	Epithelial cells detach preferentially
		Drug resistance, selective markers, serum-free selective media

and phenotypic expression and other cellular processes but also to the production of biopharmaceuticals. Now, with the elaboration of the correct substrates or scaffolds and the ability to tune the microenvironment, it has become a reliable resource of material for tissue reconstruction and grafting. The various aspects of this are discussed in other chapters, and it is the role of this chapter to fill in some of the background detail on the basics of cell culture.

### Initiation of the Culture

There are several ways to isolate cells or tissue to initiate a culture (Table 12.1). The following are the commonest methods.

1. *Primary explantation.* A fragment of tissue is placed at a solid–liquid interface and allowed to adhere, and the outgrowth of cells from the explant is collected enzymatically and subcultured (Fig. 12.1). It is a very gentle method, suitable for small amounts of tissue, but has a low yield.
2. *Enzymatic disaggregation.* Finely chopped tissue is subjected to proteolysis, usually in low  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ , to digest the extracellular matrix and dissociate junctional complexes. This method has a high yield, but some cells may be sensitive to the action of the protease. This can be reduced (a) by exposing to enzyme at  $4^{\circ}\text{C}$  for a prolonged period followed by a short incubation at  $37^{\circ}\text{C}$ , or (b) selecting enzymes that are less aggressive, e.g., collagenase or Dispase. These enzymes often give poorer cell dispersal, but that can be an advantage, particularly with epithelial and endothelial cells, where clusters of cells can be separated by sedimentation from dispersed stromal cells and often survive better than single cells.
3. *Mechanical disaggregation.* The tissue is dispersed by repeated pipetting or syringing or by forcing it through a plastic or metal mesh or screen. Mechanical disaggregation is useful for large amounts of tissue, particularly where the cells required are not strongly adherent,

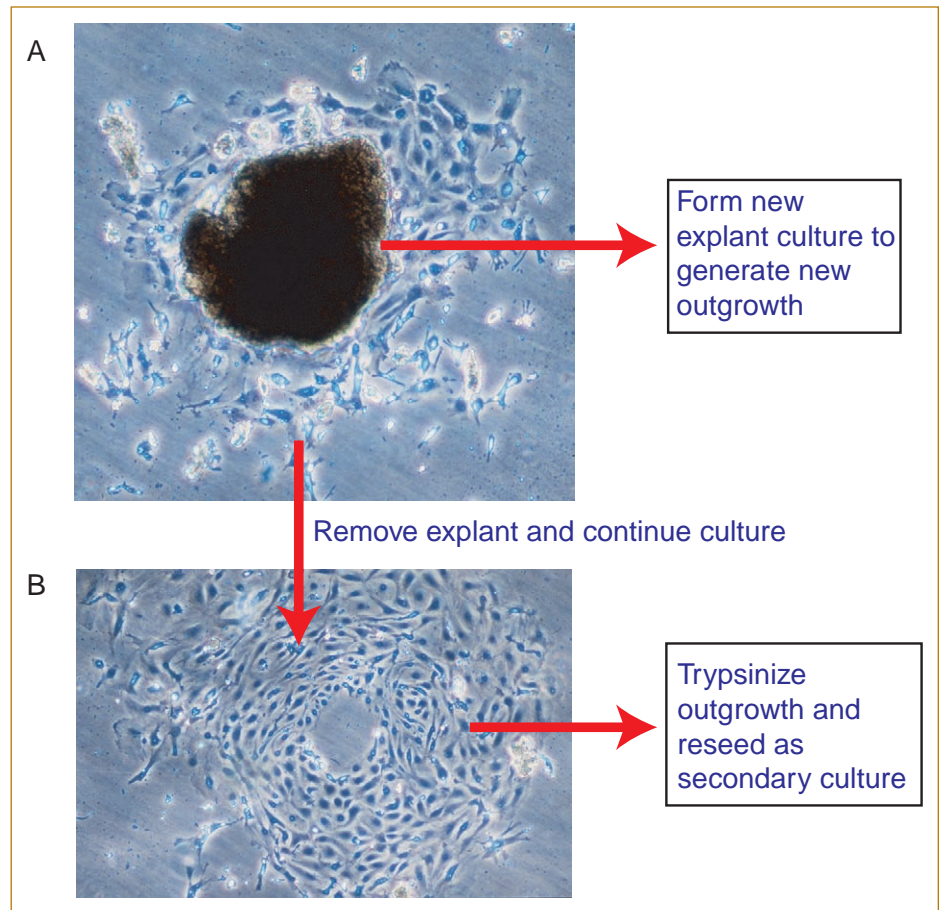

e.g., hematopoietic cells from bone marrow or spleen or tumor cells from soft, highly anaplastic tumors.

### Primary Culture

The cells that grow out from an explant or attach to the substrate after enzymatic or mechanical disaggregation are referred to as the *primary culture*. In some cases, e.g., some hematopoietic cells, pleural effusions, or ascites, the cells may survive in suspension and not attach.

The primary culture will contain a selection of cells from the tissue, dependent on their ability to migrate out of the explant or adhere after disaggregation. At this stage the culture's cellular heterogeneity is closest to that of the tissue but still by no means totally representative, for many of the cells will not survive, either because they cannot attach or because they are unsuited to the isolation medium. The most important component of these is the differentiated cell pool, which may require highly specialized conditions to survive and is unlikely to proliferate. Those cells that survive best tend to be progenitor cells, either stem cells, present in very small numbers, or committed precursor cells. This is evident when embryonic tissues are compared with adult, where embryonic tissues will give a much higher survival, particularly from younger embryos.

Clearly there is considerable selection during the primary culture phase (see Table 12.1), and this selection is further enhanced when the cells start to proliferate. Cell proliferation will be restricted to precursor and stem cells, and, given that the culture medium has often been selected for its growth-promoting ability, this leads to the amplification of the precursor compartment. There is usually little cell differentiation, and the stem cells may or may not regenerate. Because the cycle time of the stem cells is usually quite long ( $\sim 36$  h), they will tend to be diluted out by the more rapidly dividing precursor cells. Some cells may enter the precursor pool from the differentiated cell pool, e.g., differentiated hepatocytes after partial hepatectomy (although their propagation *in vitro* is still difficult), fibro-

**FIG. 12.1.** Propagation of primary explant. Appearance of primary explant culture about one week after explantation. **(A)** Explant (dark area) with cells growing out from it. **(B)** Outgrowth with explant removed. There are two methods of subculture or passage: (1) The explant may be reseeded to generate a second outgrowth; (2) the outgrowth may be trypsinized and reseeded. Modified from Freshney (2005), Fig. 12.6.

cytes may convert to fibroblasts, and vascular endothelial cells may reenter the cell cycle.

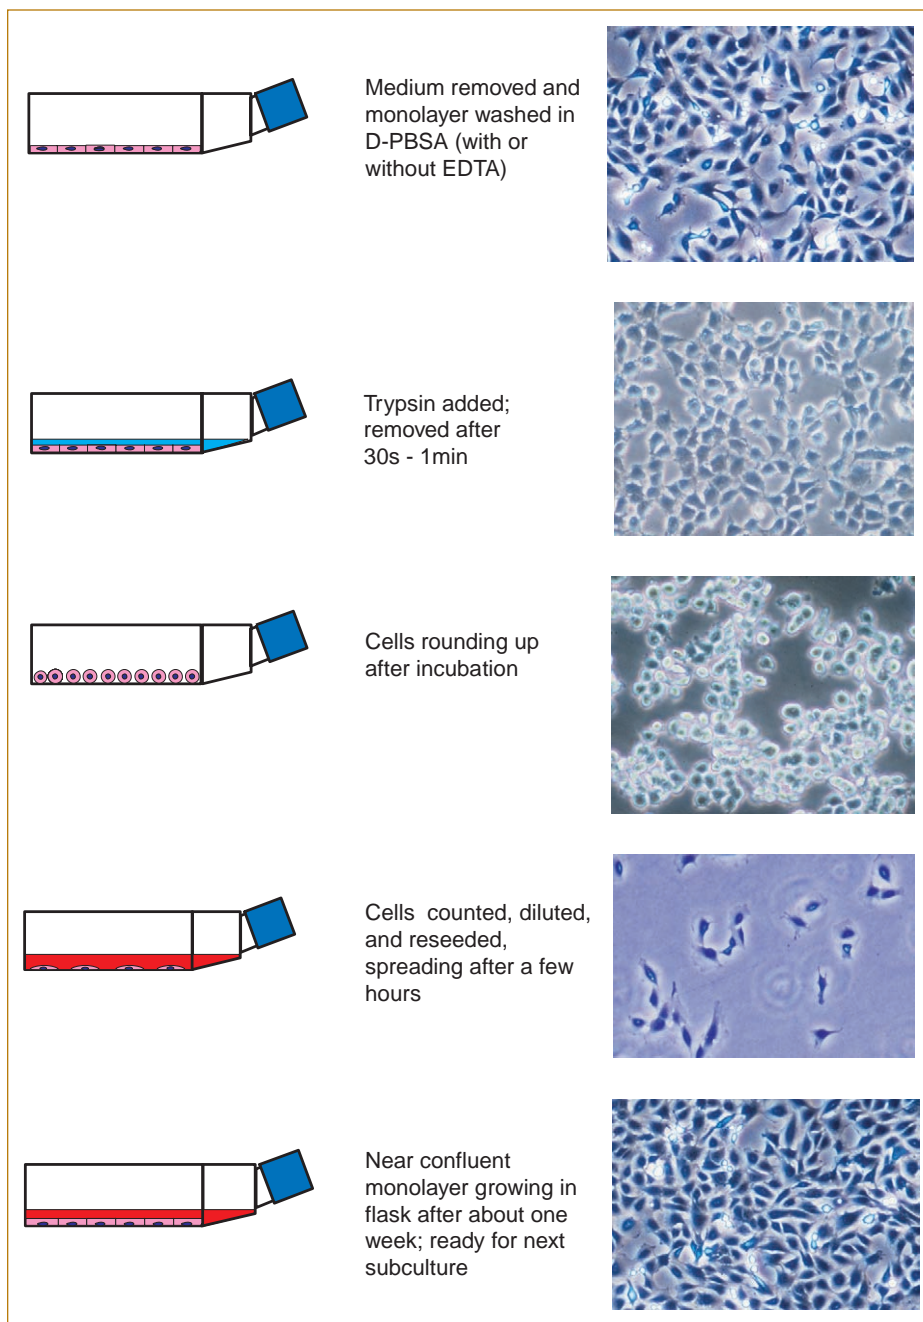

While a high proportion of the cells in an embryo may survive and proliferate in culture, in the adult the tissue is dominated by the differentiated cell compartment, and the frequency of proliferative cells may be quite low and that of stem cells very low. Although vascular and connective tissue cells may enter the cycle quite readily and come to dominate the culture, specialized lineages of cells will often require very stringent conditions in order to survive, proliferate, and, ultimately, differentiate. The size of the proliferative (or potentially proliferative) compartment will vary from tissue to tissue, but in general it may be between  $10^{-2}$  and  $10^{-4}$  of the total cell mass, while the size of the stem cell compartment will be even smaller ( $10^{-7}$ – $10^{-9}$ ). This has necessitated the development of purification and selection techniques capable of amplifying the desired population of cells and minimizing stromal overgrowth. These procedures may involve selective isolation and physical cell separation applied at the primary culture stage and selective culture conditions applied at primary culture and at each successive subculture. Typically, isolation may involve collagenase digestion, which is less aggressive than trypsinization, followed by purification. Density-gradient separation allows

for partial purification and has been used for the enrichment of mesenchymal stem cells (Lennon and Caplan, 2006; Gregory and Prockop, in press) but will often require being supplemented with, or replaced by, magnetic sorting (MACS) (Zborowski *et al.*, 1999) and/or flow cytometry (FACS) (Levenberg *et al.*, 2006) if antibodies to cell surface markers are available.

### Subculture and Propagation

When the entire growth surface is occupied (or when the concentration of the cells growing in suspension exhausts the medium), the culture may be transferred to a fresh culture vessel, or *subcultured*. If the cells grow in suspension, this simply means diluting the cells into fresh medium; but if the cells are adherent, then they must be dislodged, usually by trypsinization (Fig. 12.2). This process, also referred to as *passage*, exerts additional selection pressure (see Table 12.1), for only those cells that can survive the trypsinization process will be carried forward. Also, because an increase in cell number is usually the criterion for subculture, the process favors proliferating cells; and with each successive subculture, the growth fraction increases until by the third passage it usually exceeds 90%.

**FIG. 12.2.** Trypsinization and subculture. Standard method for trypsinization and reseeding of attached monolayer cells. Modified from Freshney (2005), Fig. 13.3 and Plates 4 and 5.

Once a primary culture is subcultured it becomes a *cell line* (Table 12.2). If it dies out after a set number of population doublings (senesces), it is referred to as a *finite cell line*. If it survives indefinitely, either without change or following transformation or immortalization (spontaneous or induced), it is referred to as a *continuous cell line*. If it is selected, either by cloning or by physical cell sorting, to produce a purified cell line with defined characteristics, it is referred to as a *cell strain*.

Senescence is regulated by a number of dominantly acting genes (Sasaki *et al.*, 1996) some of which negatively regulate the enzyme telomerase. Telomerase maintains the length of the telomeres, the shortening of which accompa-

nies senescence, and is found to be active in stem cells, which often have a longer life span in culture than normal somatic cells (Flores *et al.*, 2006). However, MSCs have been shown to lose telomerase with extended culture (Izadpanah *et al.*, 2006), and this has led to immortalization by telomerase transfection (Serakinci, 2005), which may prove to be a valuable tool in the expansion of adult stem cell lines (Shay and Wright, 2005) (see next subsection, on transformation and immortalization).

### Sourcing Cell Lines and Cell Strains

Ethical and regulatory considerations have limited the number of embryonic stem cell lines generated in the

**Table 12.2.** Definitions and stages of culture

<i>Term</i>	<i>Definition</i>	<i>Characteristics</i>
Primary culture	Culture period following explantation until first subculture	Heterogeneous; low growth fraction
Cell line	Culture following first subculture	More homogeneous than primary, but still multilineage; increased growth fraction
Finite cell line	Cell line with finite life span limited by entry into senescence	Mortal
Continuous cell line	Cell line with infinite life span achieved by spontaneous or induced transformation	Immortal; genetically unstable; heterogeneous
Cell strain	Purified cell line selected by cloning or physical cell separation and with defined characteristics	Homogeneous (but if continuous will become progressively heterogeneous, even if cloned)
Subculture	Transfer of culture to new vessel	Transit of growth cycle
Seeding	Inoculation of new culture vessel	Cells enter lag period
Seeding efficiency	Percentage of cells attaching and entering cell cycle after subculture	Low and variable for primary culture (0.1–50%); >90% for established* finite cell lines and continuous cell lines
Plating efficiency	Percentage of cells that will form clones in dilute culture	Index of survival; low in primary cultures; variable in finite cell lines, depending on medium; high in continuous cell lines
Saturation density	Highest density that the culture can achieve in nonlimiting medium supply	Low in normal cells; high in transformed cells
Cell density	Cells/cm <sup>2</sup> of available growth surface	Low at beginning of growth cycle, high at end; applied to adherent cultures only
Cell concentration	Cells/mL culture medium	Low at beginning of growth cycle, high at end; applied to adherent and suspension cultures; limited by nutrients and growth factors

\*Established no longer used for immortal cell lines; now called *continuous*. Now simply means that the culture grows and can be subcultured routinely.

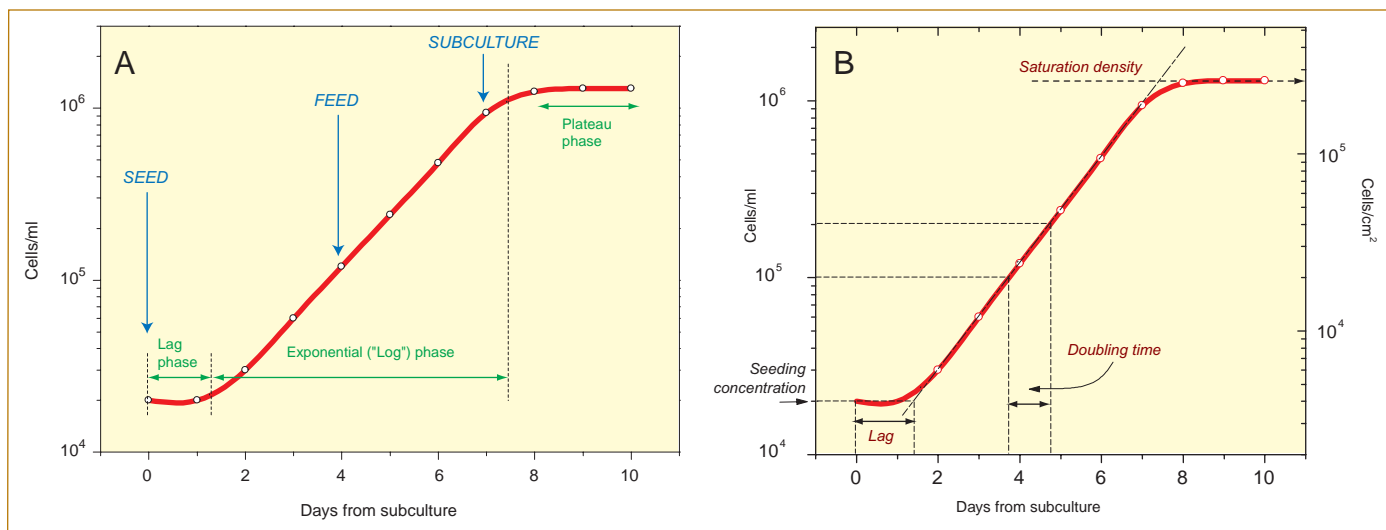

United States, but some are undergoing characterization (Loring and Rao, 2006; Plaia *et al.*, 2006; Ludwig *et al.*, 2006) and are available through WiCell [www.wicell.org/], NIH [http://stemcells.nih.gov/research/registry/], ATCC [www.atcc.org], NIBSC [www.nibsc.ac.uk/spotlight/ukstemcell.html], and ECACC [www.ecacc.org.uk]. Cell lines and cell strains are frequently obtained from collaborating institutions, for they may be the only source, but, where possible, they should be obtained from a reliable cell bank, such as those just listed, which will have performed the necessary authentication (see upcoming subsection on validation). Continuous cell lines, in particular, are subject to problems of misidentification and cross-contamination (Freshney, 2005), so it is essential to confirm the identity of any cell line that you receive if it does not come from a reliable cell bank. Even obtaining cells from the originator is no guarantee, for a survey of misidentified cell lines (MacLeod *et al.*, 1999) showed that the majority of the problems stemmed from the originator. Samples of cells received from a cell bank will

come with handling instructions (see upcoming subsection on cryopreservation). Cells should be kept in quarantine until they are shown to be free of contamination when cultured in the absence of antibiotics (Freshney, 2005).

### Growth Cycle

A growing culture is diluted when it is passaged. The degree of dilution is determined by the ability of the cells to reattach and start to proliferate (*seeding efficiency*) and is limited by the time taken to reach the density at which further subculture will be required. This not the maximum attainable density (or *saturation density*), for it is usually preferable to subculture before the cells stop growing at their saturation density.

It is important to determine both the specific cell concentration required for optimum seeding and the maximum cell concentration that would be expected before the next subculture. These data monitor the growth rate of the culture for consistency and ensure that the culture

**FIG. 12.3.** Growth of cells following subculture. Semilog plot of cell number against time from seeding. **(A)** Phases of the growth curve so produced, and times when maintenance is required. **(B)** Analysis of the growth curve, showing the derivation of the lag period, the doubling time, and the saturation density (measured in cells/cm<sup>2</sup>). Reproduced from Freshney (2005), Figs. 13.2 and 21.6, by permission of the publisher.

is always seeded at the optimal cell concentration. These critical concentrations are best determined by generating a growth curve (Fig. 12.3), at three different seeding concentrations (Freshney, 2005), once the cell line has passed the third passage, and several passages later if the cell line is to be propagated for a long time. The *lag period* (time before growth commences), the *doubling time* (time taken for the cell population to double), and the time at which the culture enters *plateau* (the period when cell number remains stable with time) can all be determined from this curve and used to establish the optimal seeding concentration and subculture interval that both are convenient and give a long exponential phase and high viable cell yield.

### Passage Number and Generation Number

Every time a culture is subcultured it advances by one *passage number*. However, most normal cell lines will survive for only a fixed time in continuous culture, and this is determined by the number of population doublings, or generations. This can be calculated at each passage from the equation  $PD = \ln(N_{\text{finish}}/N_{\text{start}})/\ln 2$ , where PD is the number of population doublings,  $\ln$  is the natural logarithm,  $N_{\text{start}}$  is the number of cells originally seeded, and  $N_{\text{finish}}$  is the total number of cells recovered at subculture (Serakinci, 2005).

However, the simplest way to deal with this is to ensure that the cells are diluted by a power of 2 at each subculture. The dilution factor is called the *split ratio*; a split ratio of 2 means that the culture will have to go through one population doubling to grow back to the same density, a split ratio of 4 ( $2^2$ ) requires two doublings, 8 ( $2^3$ ) three doublings, and so on. Finite cell lines will continue to proliferate for between 10 and 60 population doublings before they senesce, so it is important to be able to predict when the decline in growth

will occur so that fresh cultures can be initiated from primary culture or frozen stock (see upcoming subsection on cryopreservation).

### Transformation and Immortalization

Cultures of normal human cells rarely, if ever, transform spontaneously, although normal cells from many other species, particularly rodents, do so quite readily. Hence most normal human cell lines will have a finite life span unless immortalized with SV40, Ad5 E1a, HPV16 E6/E7, or EBV. Immortalization is also possible by means of transfection with hTERT, the catalytic subunit of the human telomerase gene (Serakinci, 2005; Shay and Wright, 2005), which blocks the shortening of the telomeres that accompanies senescence. Although immortal, these cell lines are not necessarily fully transformed, because their growth kinetics (anchorage dependence, growth at saturation density) are often similar to those of the finite cell line and they are non-tumorigenic. Further transformation of these lines with carcinogens or oncogene transfection can induce malignant transformation, but it appears not to happen spontaneously, although the risk has yet to be fully determined in stem cell lines.

Transformed or immortalized cell lines survive indefinitely, so recording the generation number becomes redundant, and only the passage number (usually the number of subcultures since thawing from storage) is normally recorded.

### Cryopreservation

Once a cell line has been shown to grow satisfactorily and to possess valuable characteristics, it is advisable to freeze samples in a cryostorage container, usually cooled

to  $-196^{\circ}\text{C}$  by liquid nitrogen. Initially, a token freeze of one to three ampoules is prepared; then, when characterization has been completed and the absence of contamination (see later) confirmed, a *seed stock* of 10–20 ampoules is stored. One of these ampoules is thawed, to confirm viability, identity, and freedom from contamination, and then grown up to generate a *distribution stock*, which can be issued to end users. End users may choose to prepare their own *using stock* for the lifetime of a particular project, based on serial replacement of culture stocks every three months, but these stocks should be discarded at the end of the project and not distributed to other users, because they lack proper validation.

To freeze cells for storage, they are cooled slowly ( $1^{\circ}\text{C}/\text{min}$ ) at a high cell concentration ( $(1-10) \times 10^6$  cells/mL) in the presence of a preservative (usually 5–10% DMSO or glycerol) down to below  $-50^{\circ}\text{C}$  (usually at least  $-70^{\circ}\text{C}$ ) and then transferred quickly to the cryofreezer at  $-196^{\circ}\text{C}$ . It is preferable to store ampoules in the gas phase or in perfused jacket freezers rather than submerged in liquid nitrogen, for storing in the liquid phase increases the risk of contamination of the contents and of ampoules exploding (they must be thawed in a covered container). Where human material is used, this also presents a potential biological hazard.

When required, an ampoule is selected, thawed rapidly in warm water ( $37^{\circ}\text{C}$ ), diluted at least 10-fold, and seeded into a flask. For adherent cells, it is usually sufficient to remove the preservative the following day, once the cells have attached, by replacing the medium. However, for cells growing in suspension, it is preferable to centrifuge the cells to remove the preservative before seeding. For direct seeding and for centrifugation, it is important to dilute the cells slowly in medium (at least for DMSO), for rapid dilution can lead to osmotic damage.

It is vital to ensure that proper records are kept detailing (a) the origin, characteristics, and maintenance of the cells and (b) the position of the ampoules in the freezer, how many ampoules are left in any batch, and where free spaces are to be found. It is possible to devise a simple database, e.g., in Microsoft Access, to cover this, although commercial inventory control systems are available (e.g., CryoTrack [www.cryotrack.com] and Planer [www.planer.co.uk/]).

## Validation

The term *validation* is used to imply that the cell line is safe and reliable to use. There are four main elements to validation of a cell line: authentication, provenance, characterization, and the demonstration of freedom from contamination.

### Authentication

Authentication requires confirmation of the identity of the cell line. The generally accepted method of achieving

this is DNA profiling or fingerprinting. This requires that DNA or tissue is available from the tissue donor or that an already authenticated stock exists elsewhere, e.g., in a cell bank. When deriving new cell lines, it is important to retain some tissue, even blood, from the donor, to use to confirm the origin of the eventual cell line.

### Causes of Misidentification of a Cell Line

1. Poor culture technique allows cross-contamination with another cell line to occur. Inadequate labeling allows one culture flask to be confused with another.
2. Ampoules in the cryofreezer may be inadequately or erroneously labeled or may lose their label.
3. An ampoule may be located in the wrong place or inadvertently thawed from the wrong place.

### Prevention of Misidentification and Cross-Contamination

1. Obtain cell lines from a reputable source.
2. Do not handle more than one cell line at a time.
3. Do not share media or other reagents or pipettes among cell lines or with other operators.
4. Label flasks and ampoules clearly and distinctly.
5. Do not put a pipette back into a bottle of medium or other reagent after it has been used to dispense cells or has been inside a culture flask containing cells.
6. Perform a routine visual check on all cell lines before any maintenance or experimental procedure. Keep an album, photos on the wall above the microscope, or readily accessible computerized digital images of each cell line with cells at different densities. Changes in culture morphology can often be the first indication of cross-contamination.
7. Double-check the identity of cryovials before thawing; use color coding of caps and rectangular arrays of vials to provide coordinates in the freezer, and ensure that labels are not erased or dislodged by freezing.
8. Confirm identity after thawing.

### Provenance

Each cell line should have details of how it was derived, what has been done to it (transformation, transfection, infection, decontamination, or any other manipulation, including feeding and subculture regimes and transfers to other laboratories). This makes up the *provenance* of the cell line. Although trivial at the time observed, some events may prove important in retrospect, if a cell line becomes an important resource, so careful record taking is essential. Daily written records should be summarized in a database.

### Contamination

Microbial contamination remains one of the major recurring problems in cell culture, although, given strict control of technique and environment, occurrences should be infrequent. Most media reagents and plastics are obtained

**Table 12.3.** Criteria for characterization and authentication

Criterion	Method	Reference
Karyotype	Chromosome spread with banding	Rothfels and Siminovitch (1958); Rooney and Czepulkowski (1986)
Isoenzyme analysis	Agar gel electrophoresis	Hay (2000)
Cell surface antigens	Immunohistochemistry, flow cytometry	Burchell <i>et al.</i> (1983, 1987); Hay (2000)
Cytoskeleton	Immunocytochemistry with antibodies to specific cytokeratins	Lane (1982); Moll <i>et al.</i> (1982)
DNA fingerprint	Restriction enzyme digest; PAGE; satellite DNA probes	Jeffreys <i>et al.</i> (1985); Hay (2000)
DNA Profile	PCR of microsatellite repeats	Masters <i>et al.</i> (2001)

Modified from Freshney (2005), Table 16.1.

presterilized, and excellent handling protection is provided by a laminar flow hood. Even without antibiotics, the frequency of contamination should be low. When it does occur, it is caused most frequently by lapses in technique, overcrowding, or faulty or poorly maintained equipment. Laminar flow hoods must be serviced regularly (every six months), incubators must be cleaned out frequently (every one to two weeks for a humid incubator, monthly for a regular incubator), and newcomers to the laboratory must be given proper training (Freshney, 2005) by an experienced cell culturist. The use of antibiotics should be discouraged, except in high-risk situations such as primary culture, for they tend to mask contaminations and engender careless technique.

### Characterization

The characteristics of a cell line will help to confirm its origin, in terms of cell lineage, its status (stem cell, precursor cells, or differentiated cells), product formation, virus susceptibility, or any other specialized property. Characteristics may be of general interest (e.g., cell lineage and status) or special interest to the user (e.g., drug resistance or virus susceptibility) and may also contribute to the authentication and provenance by confirming species and tissue of origin and identifying a marker property, such as high expression of a particular protein or a chromosomal abnormality. The type of characterization that is done will depend on the available technology and the use to which the cell line is put, but it is also a useful check on consistency and alerts the user to any change in the cell line that might imply contamination or transformation. Features used in characterization are too numerous to deal with here in detail and are summarized in Table 12.3.

### Differentiation

Because the conditions employed to generate cell lines tend to favor cell proliferation, most cell lines do not express the differentiated properties of the tissues from which they were derived. Historically this was blamed on *dedifferentia-*

*tion*, implying that differentiated cells grown in culture lost their differentiated phenotype. However, it is now apparent that many of the earlier attempts to grow differentiated cells, e.g., with liver, selected stromal cells rather than the functional parenchyma. Now, with selective media and a better understanding of the signaling capacity of the microenvironment, it is clear that the bulk of the cells cultured are precursor cells; although of the correct lineage, they require a shift in the culture conditions away from mitogenesis and toward cytostasis and differentiation (Table 12.4).

The factors required for differentiation can be divided into six groups (although there is a degree of overlap and interaction among them).

### Cell–Cell Interaction

- Homotypic interactions between like cells via gap-junctional communication or contact-mediated cell adhesion molecules.
- Heterotypic interactions between dissimilar cell types, such as epidermal keratinocytes and dermal fibroblasts, usually mediated by soluble paracrine factors (see later) or interaction with the extracellular matrix separating the cells (see following section).

### Matrix Interactions

Extracellular matrix forms between cells, and its constitution will depend on the cells participating in its formation. Hence the matrix laid down between an epithelial layer and an underlying mesenchymal layer will be different from that laid down between pairs of epithelial cells or pairs of fibroblasts and from that laid down between endothelial cells and astrocytes (blood–brain barrier) or endothelial cells and smooth muscle cells. These matrices contain specific protein and proteoglycan constituents, which act as ligands to receptors on the cell surface, initiating a signaling cascade that can alter cell attachment, cell shape, cell motility, and a number of other attributes, many of which are mediated via changes in gene transcription.

**Table 12.4.** Conditions favoring mitogenesis or cytotaxis and differentiation

Condition	Mitogenesis	Cytostasis/differentiation
Cell density	Low	High
Cell spreading	High	Low
Cell interaction	Low	High
Anchorage independence	In transformed cells	In normal cells
Serum	High (some exceptions, e.g., TGF- $\beta$ will favor cytotaxis)	Low
Growth factors	Mitogenic at low cell density	May induce differentiation; high cell density
Hydrocortisone	Mitogenic at low cell density	May induce differentiation; high cell density

### Soluble Factors

These fit into four main classes:

- *Inorganic ions*, particularly  $\text{Ca}^{2+}$ , which induces epithelial differentiation above 2 mM.
- *Hormones*, such as hydrocortisone (low concentrations often mitogenic, high concentrations cytotaxis and differentiation inducing, particularly at high cell densities), triiodothyronine, epinephrine, melanocyte-stimulating hormone (MSH), estrogens, and androgens.
- *Vitamins*, such as all-*trans*-retinoic acid, vitamin D3, and vitamin E.
- *Growth factors and cytokines*. These act mainly as paracrine factors, where the factor originates in one cell type and binds to receptors in a different cell type; e.g., KGF is produced by mesenchymal cells in the developing prostate but binds to receptors in the prostatic epithelium to induce growth and differentiation. Many of these paracrine interactions are reciprocal; e.g., IL-1 $\alpha$  is secreted by epidermal keratinocytes and stimulates dermal fibrocytes to make keratinocyte growth factor (KGF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), which, in turn, induces proliferation and differentiation of the keratinocytes.

The extracellular matrix plays a pivotal role in the action of many of these paracrine factors (Iozzo, 2005). Matrix proteoglycans, particularly heparan sulfate proteoglycans (HSPGs), bind growth factors, such as FGF, may stabilize them, translocate them to the interacting cell, where low-affinity transmembrane proteoglycan receptors, with no intracellular signaling domain, bind the growth factor and translocate it tangentially within the cell membrane to the high-affinity signaling receptor. These proteoglycans are themselves subject to regulation, e.g., by hydrocortisone (Yevdokimova and Freshney, 1997), adding further complexity to the interaction.

### Cell Shape and Polarity

Many cells need to adopt the correct shape and become polarized for complete differentiation to occur. The paradigm

is well illustrated by thyroid epithelium. Polarity is hard to achieve by growing cells on a solid plastic substrate. But if the cells are plated onto collagen in a filter well, the cells become crowded, less well spread (inhibiting mitosis), and more cuboidal or columnar. In this orientation the cell surface in contact with the collagen or filter becomes the basal surface, and the opposite surface becomes the apical and the sides the lateral surfaces (Chambard *et al.*, 1987). This is enabled by the tagging of newly synthesized proteins, such that some, e.g., receptors for thyroid-stimulating hormone (TSH), are directed toward the basal surface, proteins that form the junctional complex are directed to the apico-lateral membrane, and secreted proteins, e.g., thyroglobulin, are directed toward the apical surface. This does not happen unless the cell is allowed access to nutrient from below; nutrient above is not required and may even be detrimental.

In some cases, hepatocytes plated on collagen gel will show complete differentiation only if the collagen gel is detached from the substrate (Sattler *et al.*, 1978), allowing it to shrink (although medium access from below is also enhanced) and permitting the required shape change in the hepatocyte from a flattened squamous-like morphology to a cuboidal one. Clearly, several processes are involved here: shape change, withdrawal from cycle, basal nutrient access, enhanced lateral cell adhesion and junction formation, enhanced/altered integrins on the basal surface, promoting matrix interaction and binding of paracrine factors, formation of signaling receptors on the basal surface, and simulation of the equivalent of a luminal space on the nutrient-free upper side, promoting exocytosis. All of these may have implications in the construction of scaffolds to host functional transplants.

### Dynamic Stress

It is now clear that different types of dynamic stress are required to simulate the correct microenvironment for certain cell types (see upcoming section on biophysical signaling considerations). Skeletal myocytes require tensile stress (Shansky, 2006), cardiac myocytes require pulsatile

tensile stress (Eschenhagen, 2006), chondrocytes (Darling and Athanasiou, 2003) and osteocytes (Mullender *et al.*, 2004) require compressive stress, and endothelial cell/smooth muscle cell constructs require pulsatile flow (Niklason, 2006). This is not altogether surprising when one looks at the evidence *in vivo*, e.g., muscle wasting without exercise, but it is revealing to find that the physical forces can be shown to act at the cellular level rather than as a systemic effect as one might have supposed.

### Oxygen Tension

Epidermal keratinocytes will differentiate terminally only if the upper side of the filter well construct is not submerged (Maas-Szabowski *et al.*, 2002). Likewise, bronchial epithelium will differentiate into mucus-secreting cells if at the air–liquid interface (ALI), but it will undergo squamous differentiation at the solid substrate/liquid interface (Karttinen *et al.*, 1993; Dobbs *et al.*, 1997). It is assumed that the higher oxygen tension achievable at the ALI is the main factor, but other influences, such as surface tension, may also play a part.

The processes of cell differentiation and functional assembly during embryogenesis, early development, and tissue remodeling in an adult organism are directed by these six groups of factors acting in concert. In most cases, multiple molecular and physical factors are presented to the cells in the form of rather complex spatial and temporal sequences. It is thought that the cell differentiation and the functional assembly of engineered tissues *in vitro* can be modulated by these same factors, by using bioreactors for the cultivation of cells on three-dimensional scaffolds. The following sections explain in more detail the principles of bioreactor design for tissue engineering and provide representative examples on how some of the differentiation factors are provided in a physiologically relevant fashion.

## III. PRINCIPLES OF BIOREACTOR DESIGN

The most fundamental, biologically inspired, approach to engineering tissues is to direct the organization of metabolically active cells into three-dimensional (3D) spatial arrangements (via hydrogels or porous scaffolds) and to establish the environmental conditions such that the cells are induced to reconstruct immature—but functional—tissues. In nature, cells are the key architects of developing tissues and organs. Once they are provided with suitable environments, they remodel their immediate microenvironments and also integrate into a functional whole via homotypic or heterotypic interactions with neighboring cells. In both *in vivo* (development/regeneration) and *in vitro* (tissue engineering) settings, the cues with which cells are presented are the principal determinants of the phenotypic nature of the resultant tissues. Hence, for tissue-engineering applications extraordinary efforts have been expended to character-

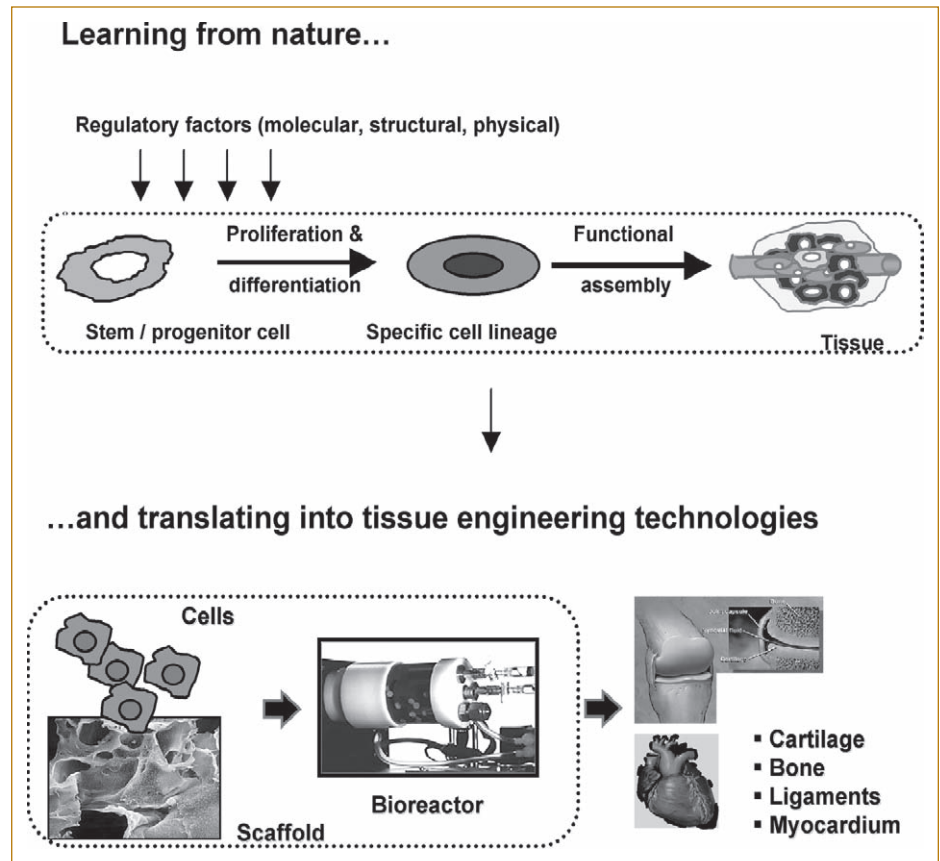

ize the native environments of these tissues and express them as a combination of parameters that may be recapitulated experimentally. Bioreactors are the primary tools for mimicking these environments and provide cell-based constructs with physiologically relevant stimuli that facilitate and orchestrate the conversion of a “collection of cells” into a specific tissue phenotype (Fig. 12.4).

Two general classes of bioreactors germane to our objectives are described. The first is the tissue-engineering bioreactor, which incorporates a quantitative understanding of both the native environments and structural characteristics of the tissue into its overall design. Thus, tissue-engineering bioreactors are designed to precisely regulate the cellular microenvironment in order to facilitate construct uniformity and overall cell viability. Key requirements of the reactors include (1) increased cell-seeding efficiency into the 3D scaffold, (2) improved mass transfer, (3) adequate gas exchange to the bulk culture media, (4) regular replenishment of spent medium, (5) temperature/pH control, and (6) physiological stimuli (Vunjak-Novakovic *et al.*, 1996, 1998, 1999, 2002; Obradovic *et al.*, 1999, 2003). Current designs incorporate biological, mechanical, or electrical stimuli in order to exert greater influence over cellular differentiation and development into functional tissue constructs. Contemporary bioreactors are therefore custom designed to account for specific structure–function relationships, mechanisms of nutrient transfer, and physiological forces inherent in the native tissue.

The second class of bioreactors is aimed at optimizing process variables prior to actual tissue-engineering applications. They are utilized primarily for screening purposes and are particularly advantageous for the economy of cells required as well as for investigating the physiological ranges of parameters and their synergistic effects. These bioreactors are typically designed to be modular, miniscaled, and multiparametric. The 3D spatial organization of cells in these reactors is not critical, and they typically are not cell or tissue specific. For example, systems may be used to investigate the effects of oxygen levels or shear stresses on the survival, proliferation, or interactions of cells on planar surfaces. As a consequence of the modular design, these systems may also test a range of these parameters to optimize conditions on small scales prior to use in larger tissue-engineering reactors, where cell numbers are generally orders of magnitude higher and culture times are longer, making them less pragmatic for screening and optimization studies.

Various examples of both types of reactors are provided in the subsequent sections of the chapter. They not only illustrate how the universal requirements are incorporated into the design, but emphasize how design specificity and relevance are influenced by tissue types. These reactors diverge considerably from “bioreactors” used in the pharmaceutical industries, where, for example, the kinetics of biological growth (unicellular organisms) or chemical reac-

**FIG. 12.4.** Biomimetic approach to tissue engineering. **(Top panel)** Cell fate and tissue assembly during early development and tissue remodeling in an adult organism are regulated by multiple cues acting across different-length scales and time sequences. Please see Table 12.4 for a description of the differentiation factors. **(Bottom panel)** Tissue engineering attempts to mimic the cell context present *in vivo* by culturing cells on biomaterial scaffolds (providing a structural and logistic template for tissue development) in bioreactors (providing an environment and regulatory signals necessary for functional tissue assembly). Adapted from Gerecht-Nir *et al.* (2006), Figs. 1 and 2.

tions are well defined and the relationship between the yield or quality of a product is well correlated to changes in specific parameters. In the tissue-engineering system, the quality of the cell population, the spatial organization of the cells, and the effects of parametric variables are all components of the culture microenvironment that interact in complex ways to influence the biochemical, phenotypic, or mechanical characteristics of the resultant tissue. Thus, the ability to provide exquisite control of the cellular microenvironment by precise manipulation of process parameters is essential to successful tissue engineering.

### Mass Transport Considerations

Compared to two-dimensional (2D) monolayer cultures, 3D constructs impose more stringent requirements for efficient mass transport to cells in order to achieve tissue uniformity and avoid widespread cell death in the inner regions of scaffolds. Nutrients, oxygen, and regulatory molecules have to be efficiently transported from the bulk culture medium to the tissue surfaces (external mass transfer) and then through the tissue to the cells (internal mass transfer). Similarly, metabolites and  $\text{CO}_2$  are removed from the cells through the tissue matrix to the surfaces and then to the bulk medium. External mass transfer rates depend primarily on hydrodynamic conditions in the bioreactor. In contrast, internal rates may depend on a combination of

diffusion and convection (induced by medium perfusion or scaffold deformation due to imposed mechanical loads) and may depend significantly on the scaffold/tissue structure. Integrated design of bioreactor configuration and biomaterial support is aimed at mimicking the *in vivo* mass transfer mechanisms and cellular microenvironment specific to the tissue structure.

Controlled delivery of nutrients and bioregulatory molecules in stem and primary cell cultures is essential to induce the expression of a desired cellular phenotype. However, in this section the primary focus is on the efficient mass transport of oxygen, because of its importance as a metabolic and signaling molecule and because it poses a challenging transport dilemma due to its extremely low solubility in aqueous media, with concentrations reaching up to  $220\ \mu\text{m}$  for fully oxygenated culture medium at  $37^\circ\text{C}$ . For comparison, oxygen concentration in blood plasma is  $130\ \mu\text{m}$ , but the total oxygen concentration in oxyhemoglobin can be as high as  $8600\ \mu\text{m}$ . Oxygen transfer is limiting even in conventional 2D tissue culture (Randers-Eichorn *et al.*, 1996) and becomes critically inadequate when cells adopt 3D structures (Martin *et al.*, 2004; Muschler *et al.*, 2004), and the diffusional penetration depth of oxygen within native tissues is in the range of  $100\text{--}200\ \mu\text{m}$  (Muschler *et al.*, 2004). Typically, tissue-engineering bioreactors are designed to improve external mass transfer

of oxygen. However, internal mass transfer mechanisms should reflect the particular characteristics and functions of the tissue.

In this section we describe approaches to bioreactor design with appropriate mass transport for engineering of two tissue types (cartilage and myocardium) with distinctly different structures and requirements for oxygen supply. Native cartilage (an avascular tissue with low cell density and low consumption of oxygen per unit volume) is supplied with oxygen by a combination of diffusion and loading-induced convective flow through the tissue. Therefore, the systems for cartilage tissue engineering rely largely on convection around the constructs and molecular diffusion within constructs, with a few examples of loading-enhanced transport rates. In contrast, cardiac muscle consists of densely packed cells that are highly metabolically active and are supplied by oxygen via a dense capillary network that reduces the diffusional distances to only 10–20  $\mu\text{m}$  and thereby increases the transport rates of oxygen. In addition, the oxygen-carrying capacity of blood is increased by several orders of magnitude by hemoglobin within red blood cells. Therefore, tissue engineering of cardiac muscle that contains physiologic cell density over clinically relevant thicknesses necessarily involves oxygen supply by a combination of convection and diffusion (by perfusion of culture medium through channeled scaffolds seeded with cells and diffusion through the tissue between channels) and the use of oxygen carriers that increase the capacity of culture medium for oxygen. For both cartilage and cardiac muscle, the bioreactor systems contain a gas exchanger that supplies oxygen to the culture medium and removes carbon dioxide. The selection of the exact conditions of bioreactor cultivation that provide the necessary level of oxygen transport is in both cases supported by the use of mathematical models of oxygen supply and consumption within the cultured tissue.

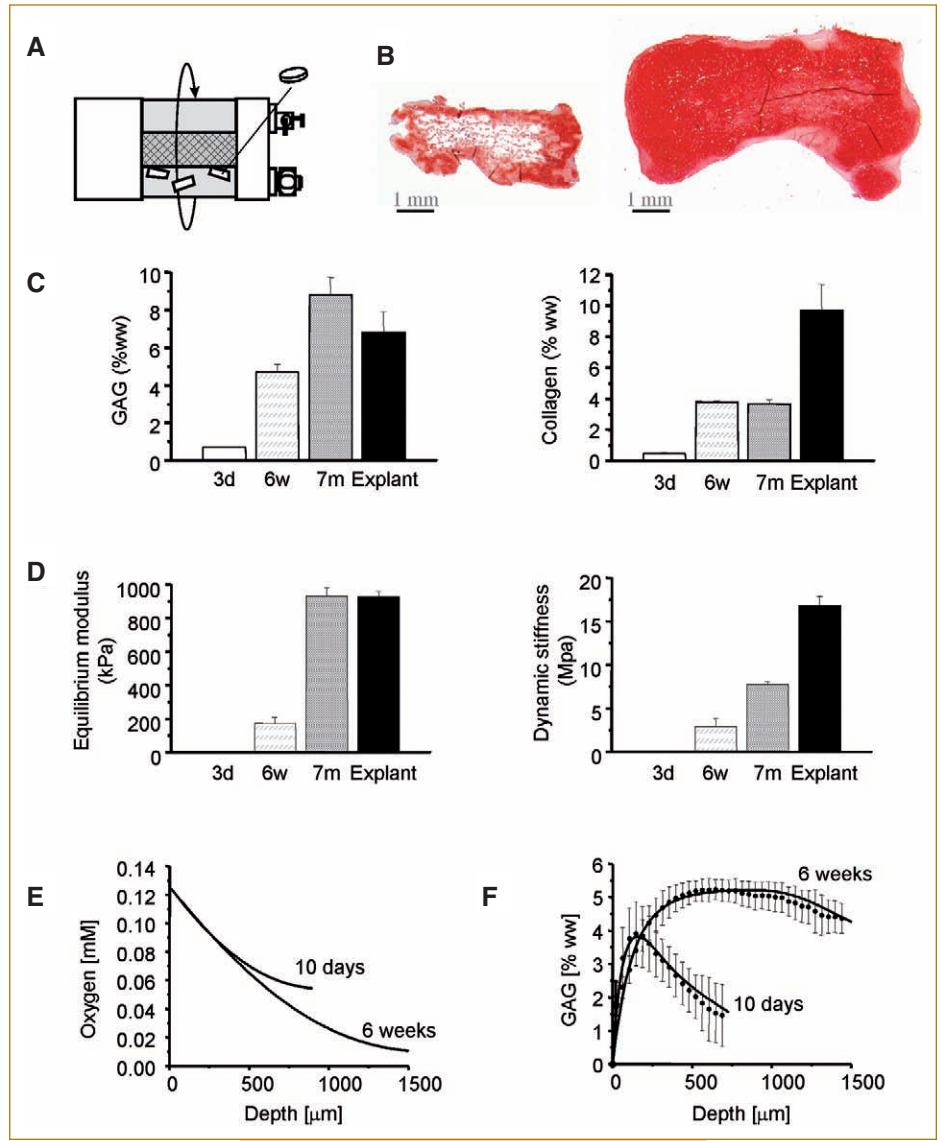

#### Example 1. Engineered Cartilage: Diffusional Transport of Oxygen

Skeletally mature articular cartilage is an avascular tissue that is supplied by oxygen and nutrients from the synovial fluid by a combination of molecular diffusion through the tissue and “physiologic pump” transport associated with joint loading and cartilage deformation during normal activities (O’Hara *et al.*, 1990). Concentrations of dissolved oxygen range from 45 to 57 mmHg at the cartilage surface to less than 7.6 mmHg in the deep zone (Brighton and Heppenstall, 1971; Urban, 1994). Chondrocytes are therefore well adapted to hypoxic conditions and provide normal turnover of the cartilaginous matrix in healthy tissue. However, adult cartilage under physiologic conditions has practically no capacity for self-repair following injury. In contrast, immature cartilage is vascularized and efficiently supplied with oxygen and nutrients and exhibits high biosynthetic activity.

The relatively low oxygen requirements of cartilage can be met using bioreactors that (1) control the level of oxygen in culture medium (via gas exchange with incubator air), (2) eliminate external gradients via convective transport around the tissue surfaces, and (3) allow diffusional transport between the construct surfaces and inner tissue phase. Rotating bioreactors are an example of a system that can provide oxygen transport in a manner that promoted chondrogenesis (Obradovic *et al.*, 2000). Engineered tissue constructs formed by seeding cells into highly porous polymer meshes or sponges were freely suspended in the rotating flow of culture medium between two concentric cylinders, where the inner cylinder was covered by a silicone membrane providing continuous gas exchange with the incubator gas (Fig. 12.5A). The vessel rotation rate was adjusted to maintain each construct settling at a stationary point within the vessel. The flow conditions were dynamic and laminar, with tissue constructs settling in a tumble-slide regime associated with fluctuations in fluid pressure, velocity, and shear (Freed and Vunjak-Novakovic, 1995). Mass transport between the tissue constructs and culture medium was enhanced by dynamic laminar convection, whereas the transport within the tissue remained governed by molecular diffusion.

Under normal oxygen tensions (~80 mmHg) in the culture medium in rotating bioreactors, engineered constructs progressively deposited ECM components over the cultivation time (Fig. 12.5B). Chondrogenesis started at the construct periphery and, over time, progressed both inward toward the construct center and outward from its surface, resulting in significant increase in the construct size and weight. By six weeks of culture, self-regulated cell proliferation and deposition of cartilaginous matrix yielded constructs that had physiological cell density and spatially uniform distributions of matrix components comprising 75% as much GAG and 40% as much total collagen (hydroxyproline) per unit wet weight as normal cartilage (Fig. 12.5B, C) (Vunjak-Novakovic *et al.*, 1999). Over prolonged cultivation for up to seven months, GAG contents exceeded physiologic levels, while collagen content remained constant (Fig. 12.5C). Biomechanical construct properties correlated with construct compositions (Fig. 12.5D) such that in seven-month constructs, both the equilibrium modulus and the hydraulic permeability became comparable with those measured for native cartilage (Freed *et al.*, 1997; Vunjak-Novakovic *et al.*, 1999), while dynamic stiffness averaged only 46% of that of native cartilage (Fig. 12.5D), suggesting the importance of a functional collagen network (Martin *et al.*, 2000).

In contrast to the cultures at normal oxygen tensions, cultivation at relatively low oxygen tensions under otherwise identical conditions in rotating bioreactors resulted in significantly lower and nonuniform ECM deposition and yielded significantly smaller engineered constructs. After five weeks of cultivation at low ( $42.7 \pm 4.5$  mmHg) and normal

**FIG. 12.5.** Cultivation of engineered cartilage in rotating bioreactors. (A) Cell-polymer constructs are freely suspended in dynamic laminar flow in the annular reactor space; continuous gas exchange is provided by the silicone membrane covering the inner cylinder, through which sterile incubator gas is blown such that oxygen tension in the medium is maintained at a constant level ( $86.5 \pm 7.3$  mmHg). (B) Progression of chondrogenesis: histological cross sections of engineered constructs cultured for 10 days and 6 weeks stained with safranin-O (Obradovic *et al.*, 2000); chondrogenesis started at the constructs' periphery and progressed both inward and outward, resulting in uniformly cartilaginous tissue at the 6-week time point. (C) Deposition of ECM over the cultivation time: contents of GAG and collagen in engineered constructs as functions of the cultivation time; data for cartilage explants are shown for comparison (data from Freed *et al.*, 1997, 1998). (D) Biomechanical properties of engineered cartilage: equilibrium modulus and dynamic stiffness as functions of the cultivation time; data for cartilage explants are shown for comparison (data from Freed *et al.*, 1997, 1998). Mathematical modeling of GAG deposition within the engineered cartilage over the cultivation time: (E) model predictions of oxygen concentrations, (F) model predictions (lines) and experimental data (symbols) of GAG concentrations (Obradovic *et al.*, 2000).

( $86.5 \pm 7.3$  mmHg) oxygen tensions, engineered constructs had  $101 \pm 8$  and  $139 \pm 12$  mg wet weight,  $3.07 \pm 0.28$  and  $4.18 \pm 0.22\%$ ww GAG, and  $0.77 \pm 0.03$  and  $2.76 \pm 0.03\%$ ww collagen, respectively (Obradovic *et al.*, 1999). Similarly, in cultures of cartilage explants, a decrease in medium oxygen tension from  $\sim 80$  mmHg to  $\sim 40$  mmHg resulted in a shift from aerobic to anaerobic cell metabolism and the suppression of tissue growth (Obradovic *et al.*, 1997).

In order to quantify the effects of oxygen on the deposition of cartilaginous matrix in engineered tissue constructs, a mathematical model was formulated that yielded concentrations of glycosaminoglycan (GAG) as a function of time and position within constructs cultivated in rotating bioreactors (Obradovic *et al.*, 2000). Production of GAG was taken as a marker of chondrogenesis, based on previous findings that GAG deposition in engineered constructs coincided with deposition of collagen type II, the other major component of cartilage tissue matrix (Freed *et al.*, 1998). The model

accounted for consumption of oxygen, synthesis of GAG as a function of the local oxygen concentration, and diffusion of both species. Due to the oxygen consumption by the cells, oxygen concentration decreased from the construct surface toward its center. The decrease in oxygen concentration was markedly higher in 6-week as compared to 10-day constructs, consistent with the increase in the total number of cells and diffusion distances with time in culture (Fig. 12.5E). The model was validated by comparing its predictions to the local GAG concentrations, measured by image processing of histological tissue sections (Martin *et al.*, 1999). Qualitative and quantitative agreements of the model predictions with experimental data for both time points were obtained (average SD =  $\pm 0.2\%$  wet weight GAG) (Fig. 12.5F). In addition, the model adequately predicted GAG concentration profiles in constructs cultivated under low oxygen concentrations in culture medium (Obradovic *et al.*, 2000). These studies indicated the importance of oxygen concentration

for GAG synthesis, in particular in the beginning of cultivation (about 10 days), and the suitability of hydrodynamically active rotating bioreactors for cartilage tissue engineering.

### Example 2. Engineered Cardiac Muscle: Convective-Diffusive Transport of Oxygen

The myocardium is a highly differentiated tissue that (via highly specialized structures) couples electrical and mechanical outputs to provide blood flow throughout the organism. It is composed of cardiac myocytes and fibroblasts with a dense supporting vasculature and collagen-based extracellular matrix. Cardiomyocytes comprise only 20–40% of the cells in the heart, but they occupy 80–90% of the heart volume. Their high metabolic activity is supported by the high density of mitochondria in the cells (MacKenna *et al.*, 1994; Brilla *et al.*, 1995) and by vast amounts of oxygen supplied by convection of blood through capillary networks and diffusion into the tissue space surrounding each capillary. Under physiological conditions, oxygen dissolved in blood plasma accounts for only ~1.5% of total oxygen content of the blood (Fournier, 1998), while the majority of oxygen-carrying capacity of the blood comes from hemoglobin, a natural oxygen carrier.

Conventional approaches to engineer cardiac tissues based on cell-polymer constructs immersed in medium flow providing convective transport of oxygen to the construct surfaces and molecular diffusion through the interior resulted in constructs with ~100- $\mu$ m-thick outer layer of viable cells and acellular or necrotic core due to hypoxia (Bursac *et al.*, 1999). In order to provide an *in vivo*-like oxygen supply to the cells within engineered cardiac constructs, a biomimetic approach based on highly porous scaffolds, culture medium supplemented with oxygen carriers, and perfusion bioreactors was developed (Radisic *et al.*, 2006) (Fig. 12.6A).

To mimic the capillary network, rat cardiomyocytes alone or in a coculture with fibroblasts were cultivated on a highly porous elastomer (Wang *et al.*, 2002), with a parallel array of channels that were perfused with culture medium at a flow velocity of 500  $\mu$ m/s (comparable to that of blood flow in native heart). In this way, convective transport within the cultivated tissue was provided.

To mimic the role of hemoglobin, the culture medium was supplemented with a synthetic oxygen carrier (Oxygent<sup>TM</sup>, perfluorocarbon emulsion). Oxygent<sup>TM</sup> is a 60% w/v (32% v/v) phospholipid-stabilized emulsion of perfluorooctyl bromide as a principal component and a small percentage of perfluorodecyl bromide (Kraft *et al.*, 1998). Since perfluorocarbon (PFC) droplets are immiscible with the aqueous phase, they served as rechargeable oxygen reservoirs. As oxygen was depleted from the aqueous phase of culture medium, it was replenished by diffusion of dissolved oxygen from PFC particles (Fig. 12.6B). Overall, the oxygen partial pressures measured in the aqueous phase of PFC-supplemented and unsupplemented (control) media were

the same, and the PFC particles replenished oxygen consumed by the cells without increasing oxygen concentration in the culture medium.

A steady-state mathematical model of oxygen distribution in the cardiac tissue construct with a parallel channel array perfused with PFC-supplemented medium was developed and solved for a set of parameters (Radisic *et al.*, 2005). The model accounted for oxygen transfer in the channels by axial convection and radial diffusion as well as for axial and radial diffusion and consumption in the tissue region surrounding the channels. Supplementation of culture medium by PFC emulsion was predicted to improve mass transport by increasing convective term and effective diffusivity of culture medium, resulting in increased total oxygen concentration (Fig. 12.6C). Model predictions were consistent with experimental results showing lower oxygen decrease in PFC-supplemented medium passing through the tissue construct (28 mmHg) as compared to the group perfused with pure culture medium (45 mmHg) (Radisic *et al.*, 2006). Higher availability of oxygen resulted in markedly and significantly higher contents of DNA and cardiac proteins as well as enhanced contractile properties of tissue constructs cultured with the PFC-supplemented medium as compared to those cultured in control medium (Fig. 12.6D–F) (Radisic *et al.*, 2006).

In sum, these examples demonstrate that the biomimetic approach to the design of 3D tissue culture systems can provide *in vivo*-like transport of oxygen, resulting in physiologic densities of viable, differentiated cells.

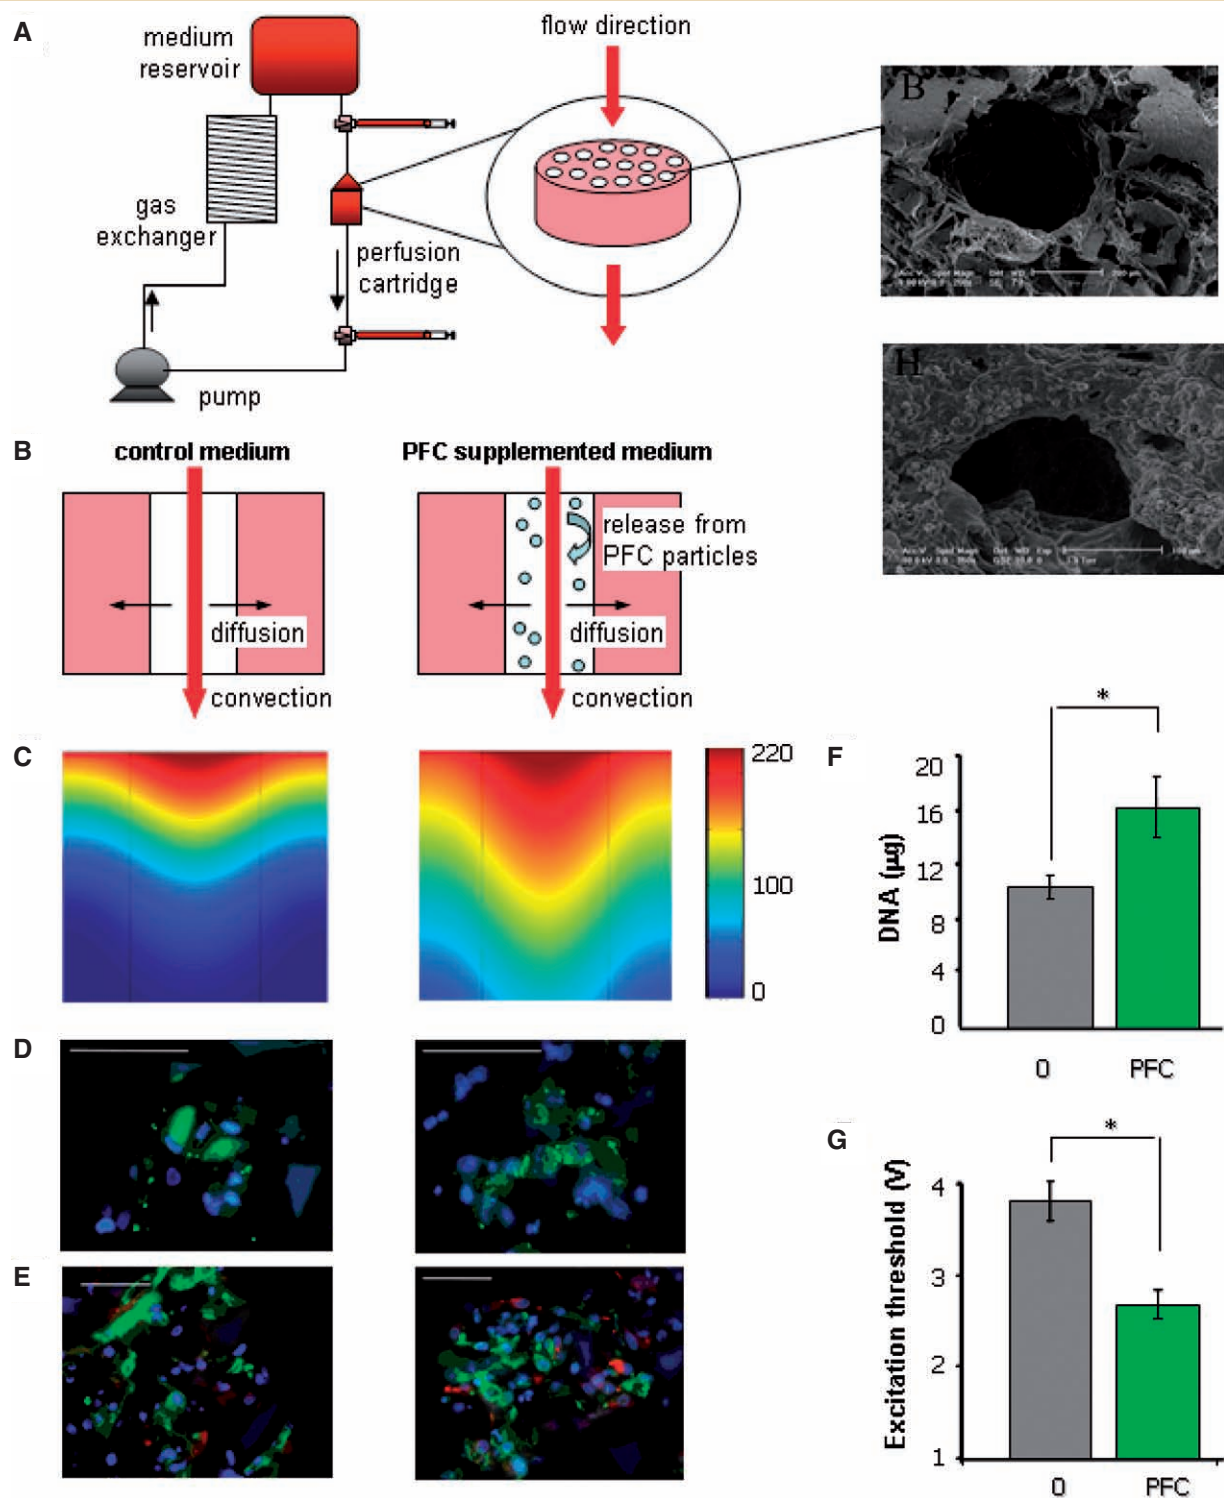

### Biophysical Signaling Considerations

Tissues and organs in the body are subjected to complex biomechanical environments with dynamic stresses and strains, fluid flow, and electrical signals. It is widely accepted that biophysical signals that play a role in cell physiology *in vivo* can also modulate the activity of cells within engineered tissues cultured *in vitro*. Innovative bioreactors have been developed to apply one or more regimes of controlled physical and/or electrical stimuli to 3D-engineered constructs in an attempt to improve or accelerate the generation of a functional tissue. In this section, we describe several examples of biomimetic approaches to engineer different tissue types under suitable biophysical regulation, with the aim to stimulate ECM synthesis, improve structural organization of the tissue, direct cell differentiation, and enhance a specific cell/tissue function.

### Example 3. Engineered Cartilage: Dynamic Compression

Articular cartilage lines bone ends in synovial joints and allows joint mobility while transferring compressive and shear forces. During joint movements, articular cartilage is dynamically exposed to compressive stresses, which can be as high as 6–18 MPa (Ateshian and Hung, 2003). Mechanical loading was shown to strongly affect metabolic activity of articular chondrocytes, consequently altering composition,

structure, and biomechanical properties of articular cartilage *in vivo* and *in vitro*. *In vivo* studies clearly showed that moderate exercise leads to an increase in the proteoglycan content of articular cartilage (Saamanen *et al.*, 1987; Kiviranta *et al.*, 1988), whereas immobilization of joints leads to a loss of proteoglycans (Palmoski *et al.*, 1979; Vanwanseele *et al.*, 2002). *In vitro* studies indicated that static mechanical compression of cartilage explants results in decreased matrix biosynthesis by chondrocytes (Larsson *et al.*, 1991; Wong *et al.*, 1997), whereas cyclic loading may stimulate synthesis of proteoglycans and proteins, in a way that depends on the frequency, intensity, and duration of the stimulus (Gray *et al.*, 1989; Sah *et al.*, 1989; Parkkinen *et al.*, 1993; Steinmeyer and Knue, 1997; Wong *et al.*, 1999; Grodzinsky *et al.*, 2000).

It is believed that suitable biomechanical stimuli mimicking those found *in vivo* are also required for functional cartilaginous tissue assembly under *in vitro* conditions. Bioreactors with controlled dynamic loading were proposed for *in vitro* cultivation of engineered cartilage (Mauck *et al.*, 2000, 2002, 2003a, 2003b; Demarteau *et al.*, 2003a, 2003b). Tissue constructs are placed in wells and dynamically compressed by plungers to mimic physiological joint loading (5–10% strain, 0.1- to 1-Hz frequency). In the experimental setup shown in Fig. 12.7A, bovine chondrocytes seeded in alginate and agarose gels (4.76- to 6.76-mm-diameter, 2.2-mm-thick discs) were cultivated for up to two months under intermittent deformational loading (10% strain, 1-Hz frequency, 1 h on/1 h off, 3 h per day, 5 days per week) at different cell densities and culture medium compositions (Mauck *et al.*, 2000, 2002, 2003a, 2003b). Mechanical loading stimulated deposition of cartilaginous ECM components in cultures that were efficiently supplied with nutrients as compared to static free swelling (Mauck *et al.*, 2002, 2003b). At the seeding density of 10 million cells/mL and the culture medium supplemented with 10% fetal bovine serum (FBS), GAG and collagen contents continually increased over the cultivation time, resulting in significantly higher wet weight fractions in mechanically stimulated constructs at six- and eight-week time points as compared to the static controls (Fig. 12.7B).

Correspondingly, mechanical stimulation resulted in significantly higher values of equilibrium Young's modulus and dynamic modulus (Fig. 12.7C). In addition, dynamic loading of cell-polymer constructs based on dually transfected bovine MSCs with an aggrecan-luciferase reporter construct and a constitutive CMV-Renilla plasmid, modulated aggrecan promoter activity, such that it increased over time, resulting in increased proteoglycan content (Mauck *et al.*, 2006). It should be noted that intermittent dynamic compression enhanced biomechanical properties of engineered constructs (Mauck *et al.*, 2002, 2003b), while no significant differences in GAG and collagen contents were measured, which implies different structural organizations of the produced ECM (Mauck *et al.*, 2003b). Growth factors provided in conjunction with dynamic loading during

culture had a synergistic effect on the compositions and mechanical properties of cultured constructs (Mauck *et al.*, 2003a).

Results of these studies suggest that dynamic deformational loading, with optimized parameters, and appropriate biochemical signals can facilitate the growth of a structurally organized cartilage tissue substitute.

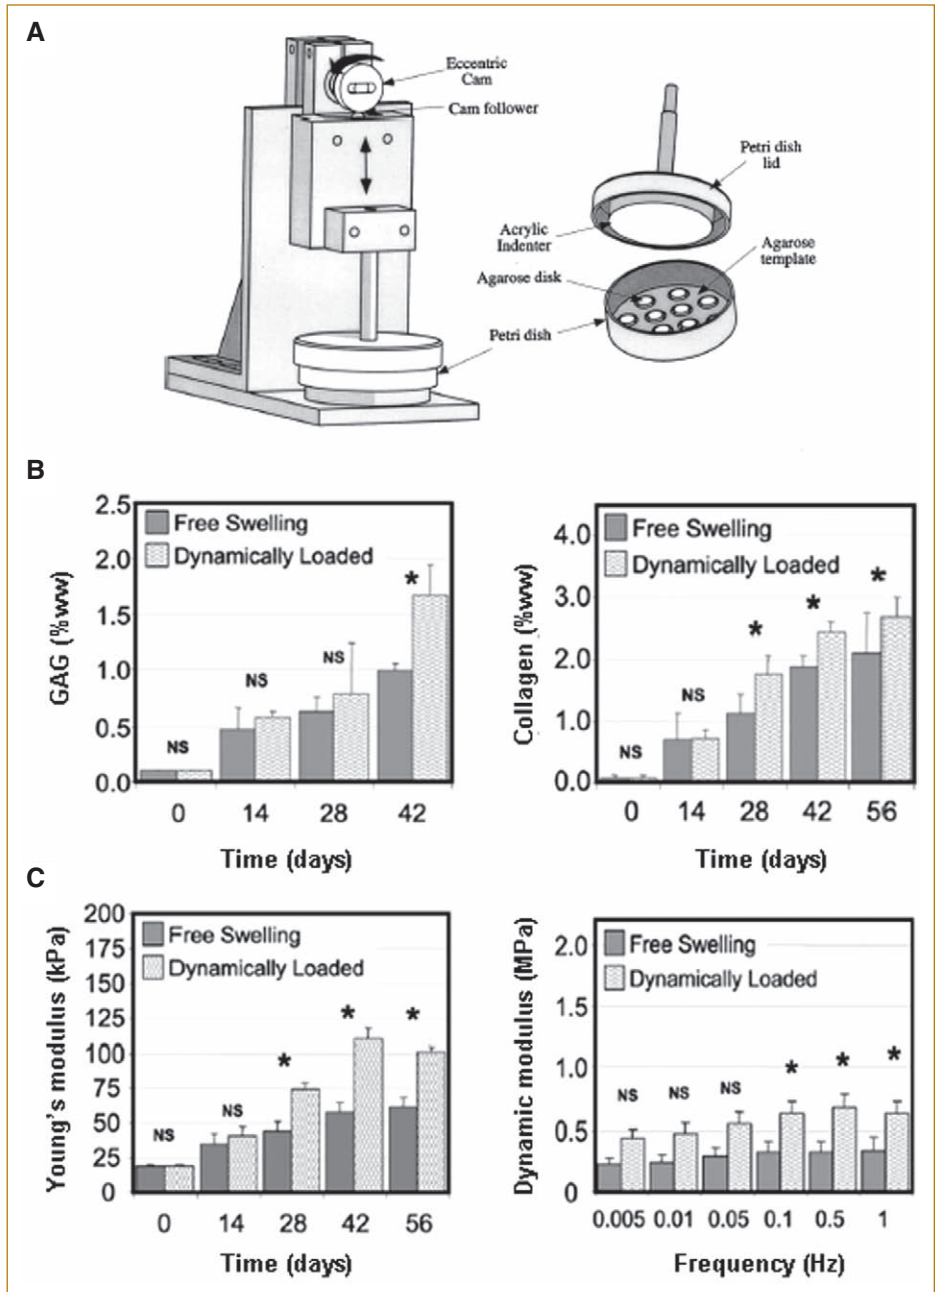

#### Example 4. Engineered Ligament: Dynamic Torsion and Tension

Ligaments consist of bundles of fibrous connective tissue that stabilize the joint and help hold it together. The anterior cruciate ligament (ACL) works with the posterior cruciate ligament (PCL) as the major stabilizing ligaments of the knee. The ACL is composed of bundles of collagen and elastic fibers oriented axially or spirally around the long axis. During knee movements, the ACL is exposed to axial tensions of 100–700 N and torsions up to 140°. It is hypothesized that suitable biomechanical environments could be used to stimulate functional assembly of ligament tissue as well as to induce differentiation of bone marrow-derived mesenchymal progenitor cells into ligament fibroblasts.

An advanced bioreactor system providing multidimensional mechanical strains (axial tension/compression and torsion) was proposed for ligament tissue engineering based on mesenchymal progenitor cells cultured on collagen or silk scaffolds. It consisted of individual cartridges containing tissue constructs, each within a separate perfusion loop (Fig. 12.8A). Cell-polymer constructs were anchored between a bottom platen fixed in place and a top platen connected to gear trains driven by motors. The bioreactor provided independent but concurrent control over axial and torsional strains imparted to the growing tissue. Axial strain (5–10%) and torsional strain (<90°) were applied via the top platen at frequencies of 0.01–1 Hz, with periods of loading and rest (e.g., 20 min of mechanical stimulation every 8 h) (Altman *et al.*, 2002a, 2002b, 2002c).

Mechanical stimulation *in vitro*, without supplementation of ligament-selective exogenous growth and differentiation factors, induced the preferential differentiation of bone marrow-derived mesenchymal progenitor cells into a ligament cell lineage. A total of 24 engineered ligaments based on bovine or human cells were cultured for up to 21 days with 90° rotational and 10% axial strain at 0.0167 Hz (Altman *et al.*, 2002b). Mechanical stimulation fostered cell alignment in the direction of the resulting force, resulted in the formation of oriented collagen fibers, and up-regulated collagen types I and III and tenascin-C, all features characteristic of ligament cells. On collagen matrices, helically organized collagen fibers (20- $\mu$ m-diameter bundles) with characteristic collagen banding patterns were formed in the direction of the applied load at the periphery of the mechanically stimulated ligaments, a feature absent in the controls (Fig. 12.8B). On silk matrices, the expression of collagen types I and III and tenascin-C was observed; the ratio of

**FIG. 12.7.** Cultivation of engineered cartilage in a bioreactor with dynamic compression. **(A)** Chondrocyte-seeded agarose discs are placed in an agarose template and subjected to unconfined dynamic compression (Mauck *et al.*, 2000). **(B)** Deposition of ECM in constructs seeded with bovine chondrocytes at  $10 \times 10^6$  cells/mL and cultured in medium supplemented with 10% FBS under free-swelling conditions or subjected to dynamic loading (10% strain, 1 Hz, 1 h on/1 h off, 3 h per day, 5 days per week): contents of GAG and collagen as functions of the cultivation time. **(C)** Biomechanical properties of engineered cartilage: equilibrium Young's modulus as a function of the cultivation time and dynamic modulus at frequencies ranging from 0.005 to 1 Hz for constructs on day 56. Dynamic compression stimulated functional ECM assembly such that dynamically loaded constructs exhibited significantly better biomechanical properties as compared to static cultures under free-swelling conditions (\* indicates  $p < 0.05$ ). Adapted from Mauck *et al.* (2003).

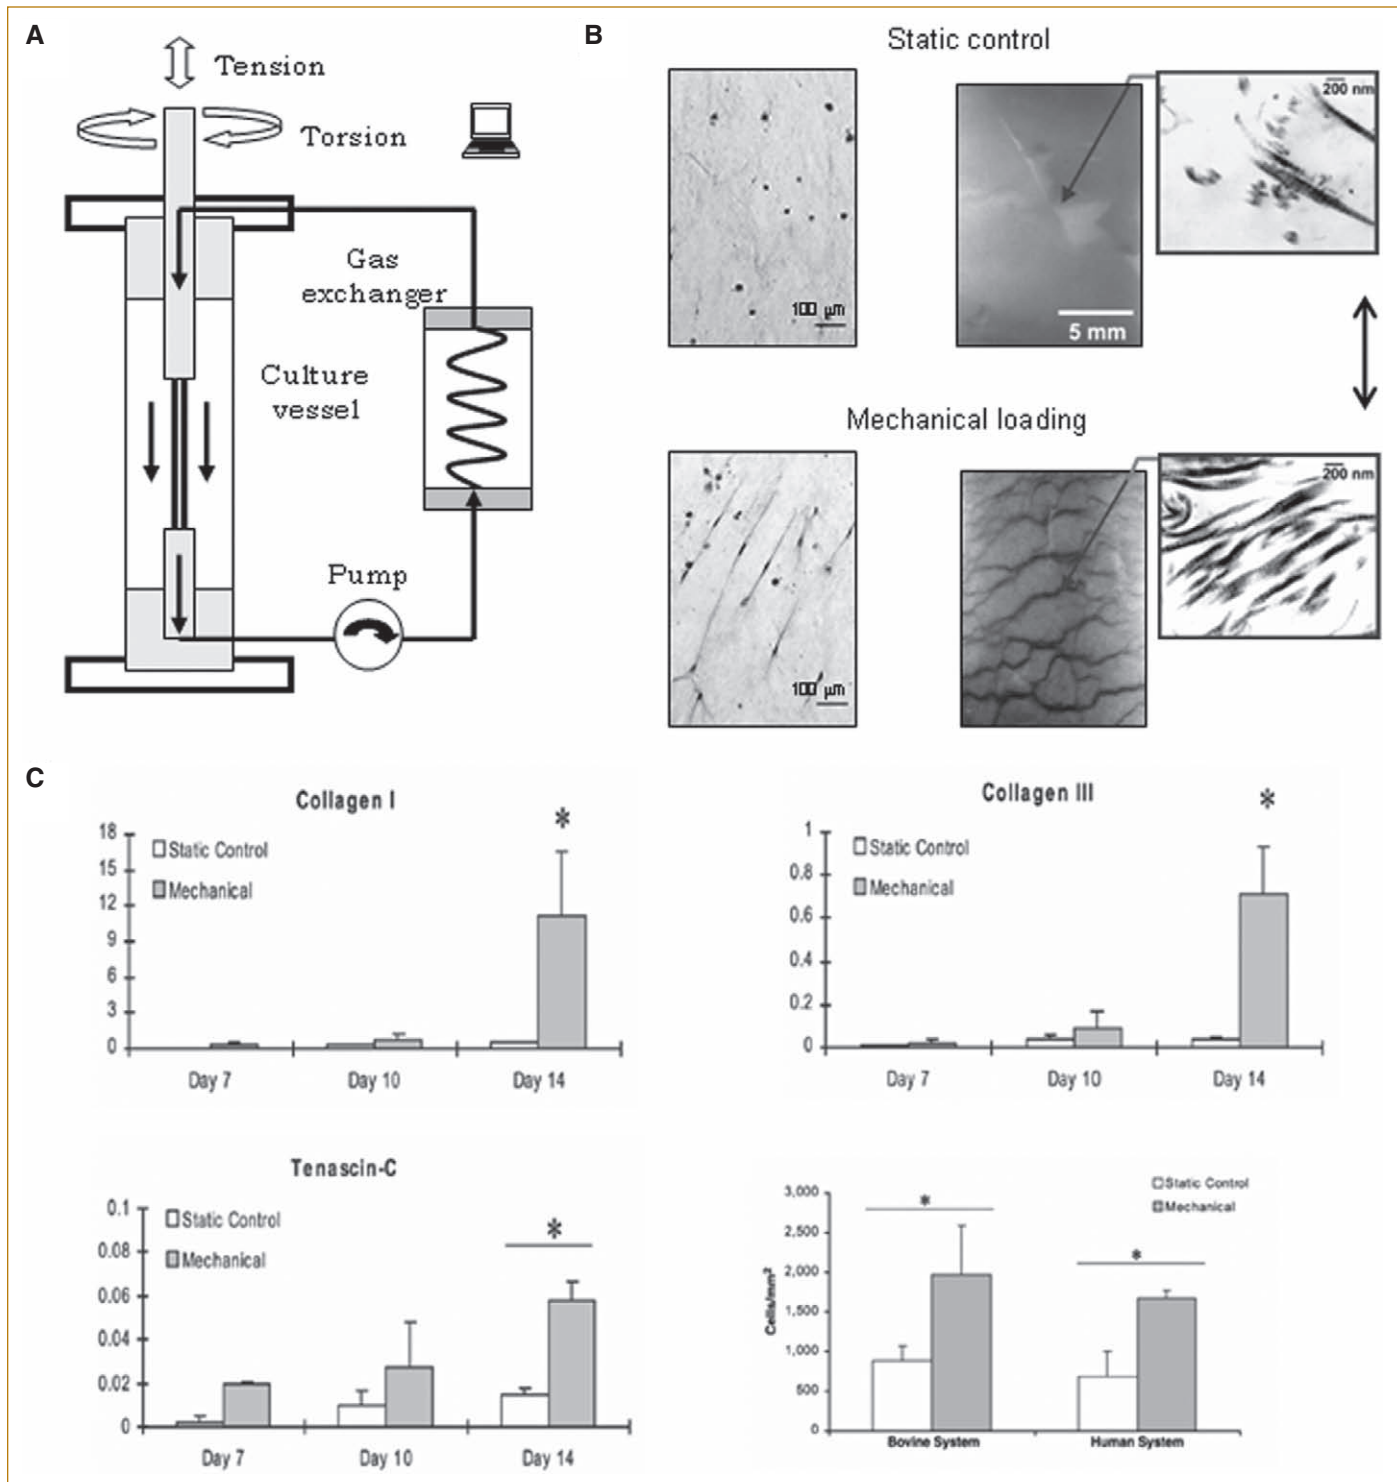

collagen type I expression to collagen type III was 8.9:1, consistent with that of native cruciate ligaments (Fig. 12.8C). At the same time, no up-regulation of bone or cartilage-specific cell markers was observed (Altman *et al.*, 2002b).

These studies support the notion that advanced bioreactors providing physiologically relevant mechanical loading are essential for meeting the complex requirements of *in vitro* engineering of functional skeletal tissues.

#### Example 5. Engineered Bone: Hydrodynamic Shear

Native bone is a load-bearing tissue with a multiplicity of roles within the organism. Notably, the composition of bone varies only a little within the skeleton. The cells are

embedded in a matrix composed of approximately 50% fibrous organic matrix (collagen, GAG, and glycoproteins) and 50% mineral (hydroxyapatite crystals and amorphous calcium phosphate). In contrast, the hierarchical organization of bone varies tremendously across distinct skeletal sites, such that the biomechanical properties also change considerably. Macroscopically, bone has a dense cortical compartment and a porous trabecular bone compartment. Microscopically, bone consists of discrete assemblies: osteons in the cortical bone and trabecular packets, with an arrangement of lamellae composed of cells embedded within the mineralized collagen type I-dominated matrix (Vunjak-Novakovic and Goldstein, 2005). To fully describe bone, it is

**FIG. 12.8.** Cultivation of engineered ligament in the bioreactor system with multidimensional mechanical strains. **(A)** Cell-polymer constructs are anchored in cartridges between two platens, the upper one of which is connected to computer-controlled gear trains to provide axial (5–10%) and torsional (<90°) strains at a specified frequency (0.01–1 Hz). Each cartridge is connected to a separate perfusion loop provided with a gas exchanger and connected to a pump. **(B)** Appearances of gels seeded with bovine bone marrow-derived cells and cultivated for 21 days in the bioreactor system under static conditions (*upper panel*) and under mechanical loading (10% axial strain, 90° torsion, 0.0167 Hz for 20 min every 8 h; *lower panel*); double-headed arrow indicates the longitudinal axis of the ligaments: longitudinal sections of gels stained with H&E (*left*) and gel images with TEM inserts (*right*). Mechanical stimulation induced cell alignment in the direction of the resulting force (45°) and collagen fiber bundle formation and organization in a helical manner at the tissue periphery. **(C)** Composition of engineered tissue over time: relative expressions of collagen type I and III and Tenascin-C in static and mechanically loaded constructs obtained by RT-PCR (\* indicates  $p < 0.05$ ) and cross-sectional cell densities of gels seeded with bovine cells after 21 days of culture and gels seeded with human cells after 14 days of culture (\* indicates  $p < 0.001$ ). Adapted from Altman *et al.* (2002a, 2002b, 2002c).

necessary to measure biomechanical properties of the tissue at multiple scales. Macroscopically, bone has a compressive modulus ranging from 10 to 50 MPa, and therefore it has the ability to withstand high levels of mechanical forces.

In the *in vivo* settings, compressive stresses have been shown to be potent anabolic stimuli during bone formation and remodeling. In contrast, a sustained absence of mechanical stimulation (e.g., microgravity) leads to significant reductions in mineral content and strength of bone. Likewise, bone cells *in vitro* respond to a variety of mechanical signals, including hydrostatic pressure and hydrodynamic shear. Paradoxically, compressive stimulation during culture has a relatively minor influence on *in vitro* bone growth and mineralization since the load is borne almost exclusively by the scaffold substrate and not efficiently transferred to the cells within the pore spaces (Owan *et al.*, 1997; Smalt *et al.*, 1997). Rather, tissue-engineered bone growth is considerably enhanced by hydrodynamic shear induced by perfusion of culture medium. It is thought that this mimics the interstitial flow in canalicular spaces during bone deformation associated with natural compressive loading. Contemporary bone bioreactors therefore are designed for direct medium flow through the construct in order to expose all cells to shear (Bancroft *et al.*, 2002; Cartmell *et al.*, 2003; Sikavitsas *et al.*, 2003; Braccini *et al.*, 2005; Holtorf *et al.*, 2005).

It has been widely demonstrated that incorporation of medium flow enhances tissue-engineered bone growth. In a well-designed series of experiments, the dose-dependent effects of perfusion/shear on osteoblasts was investigated using a system designed for direct perfusion of culture medium through six independent chambers (Bancroft *et al.*, 2002). Each chamber contained a titanium-fiber mesh scaffold sandwiched between two O-rings to ensure flow directly through the scaffold (Fig. 12.9A). Three flow rates, corresponding to superficial velocities ranging from 64  $\mu\text{m/s}$  to 640  $\mu\text{m/s}$ , were used, and the scaffolds were cultured for up to 16 days with continuous perfusion. In osteoblast culture, a direct correlation was observed between the perfusion rate and calcium deposition within the scaffolds on day 16 of culture (Fig. 12.9B). There were also increases in the alkaline phosphatase levels in perfused cultures relative to static cultures, although the enzyme activity was independent of perfusion rates. Osteopontin, a marker of early-stage osteogenesis, exhibited temporal increases in perfusion cultures. Peak osteopontin levels occurred earlier at higher perfusion rates, indicating acceleration of the osteogenic process that is flow-rate dependent.

In order to elucidate whether the effects were due to increased shear or enhanced nutrient transfer, dextran molecules were used to vary medium viscosities and obtain modified culture media with viscosities twice and three times that of the control (Sikavitsas *et al.*, 2003). Then the same flow rate ( $\sim 64 \mu\text{m/s}$ ) was used for three experimental groups to impart different shear forces (1 $\times$ , 2 $\times$ , and 3 $\times$ )

throughout the constructs without increasing levels of nutrient transfer in the various groups. Enhanced calcium deposition/matrix distribution was observed that was directly related to shear forces through the scaffolds (Fig. 12.9C, D).

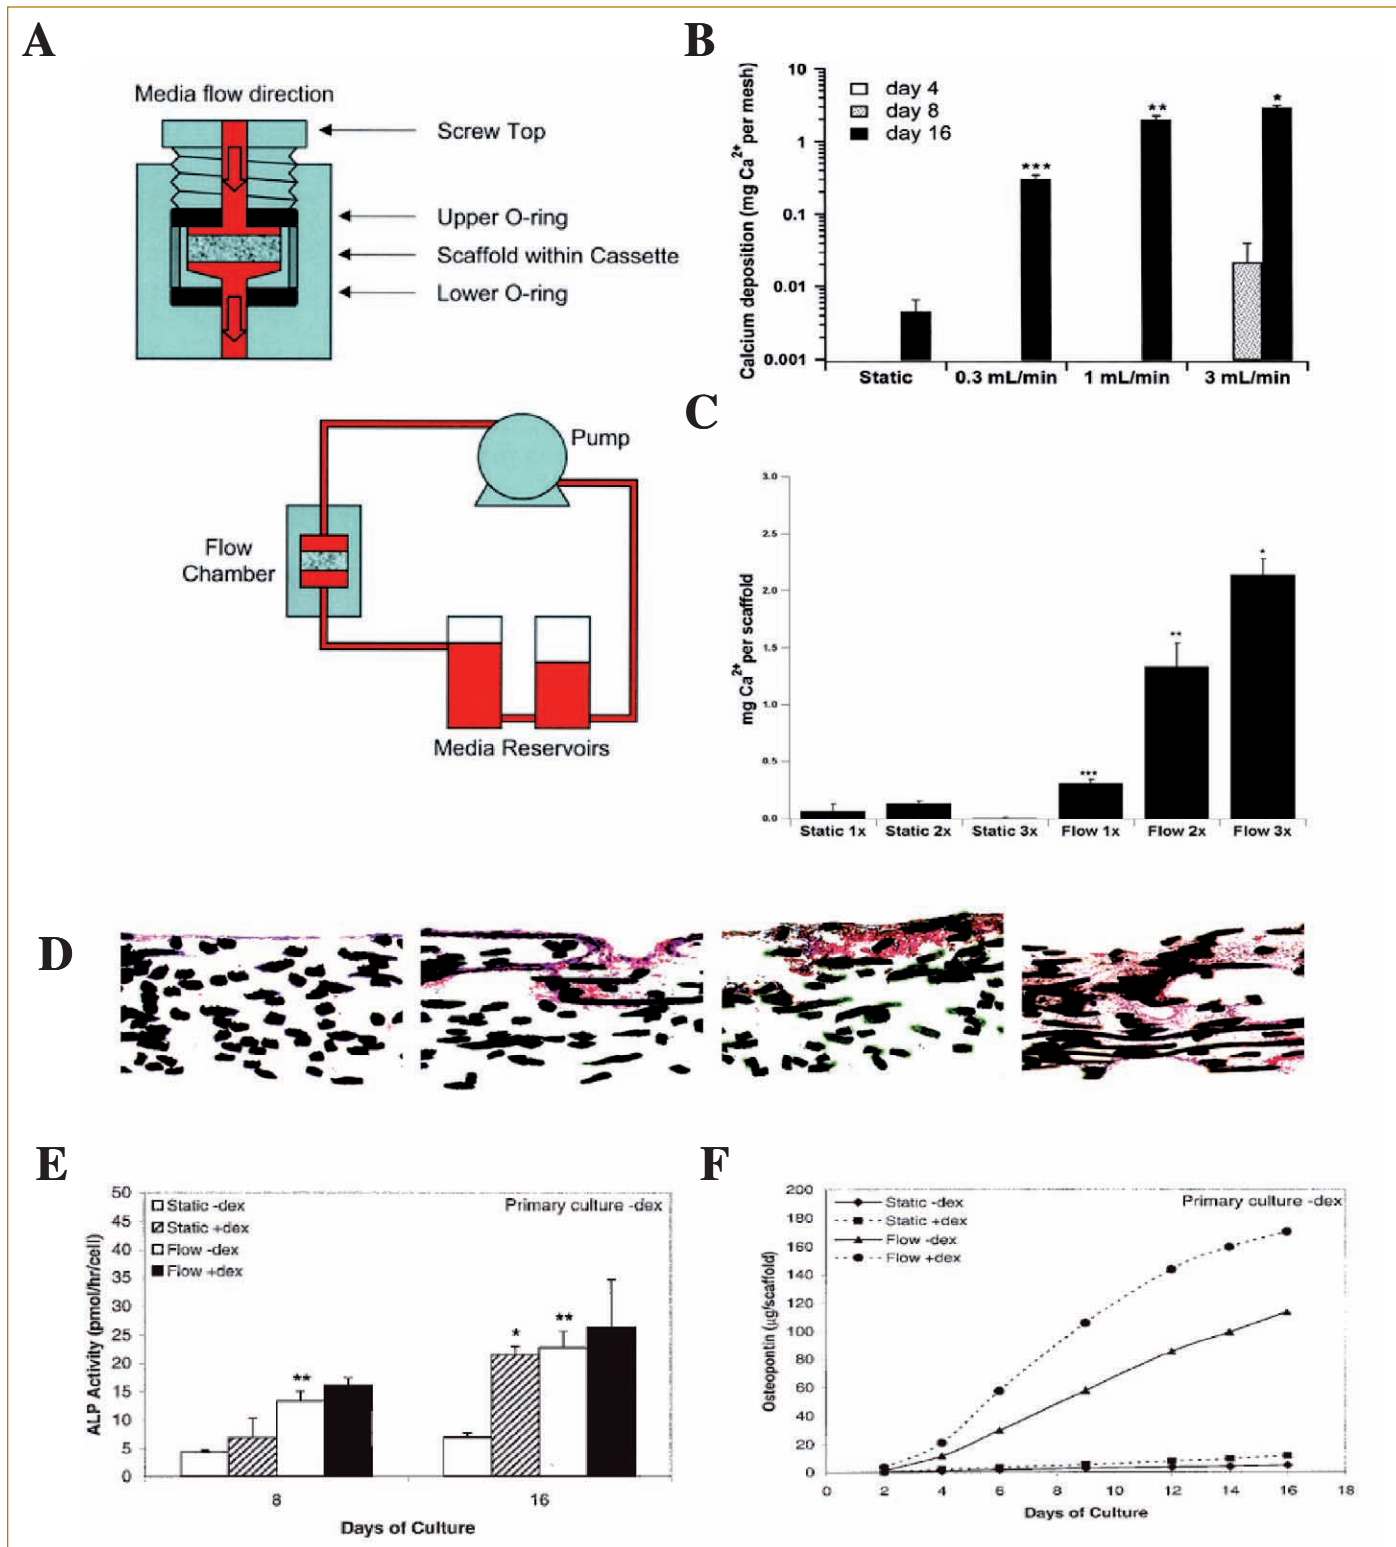

Using the identical system, marrow stromal cells were cultivated in the presence and absence of dexamethasone (a potent osteoinductive hormone) and under static and flow conditions (64  $\mu\text{m/s}$  for 1 day, 640  $\mu\text{m/s}$  thereafter) to investigate whether mechanostimulatory effects were sufficient to induce an osteoblastic phenotype (Holtorf *et al.*, 2005). Medium flow alone was sufficient to induce increased AP activity, although it appeared that peak levels were higher when both flow and dexamethasone were used (Fig. 12.9E). Similarly, flow with dexamethasone maintained greater calcium deposition relative to the other three groups, but calcium deposition also significantly increased using only flow stimulation. Osteopontin levels were only higher than the control (static, no dexamethasone) in perfused constructs (Fig. 12.9F). These results demonstrate that mechanostimulation of marrow stem cells, even in the absence of a biological stimulus, may be sufficient to induce some characteristics of a differentiated phenotype. Moreover, it emphasizes that the mechanical stimuli work synergistically with biological signals to enhance the expression of the osteoblastic phenotype and to improve the functionality of the tissue-engineered bone construct.

#### Example 6. Engineered Arteries: Pulsatile Radial Strains

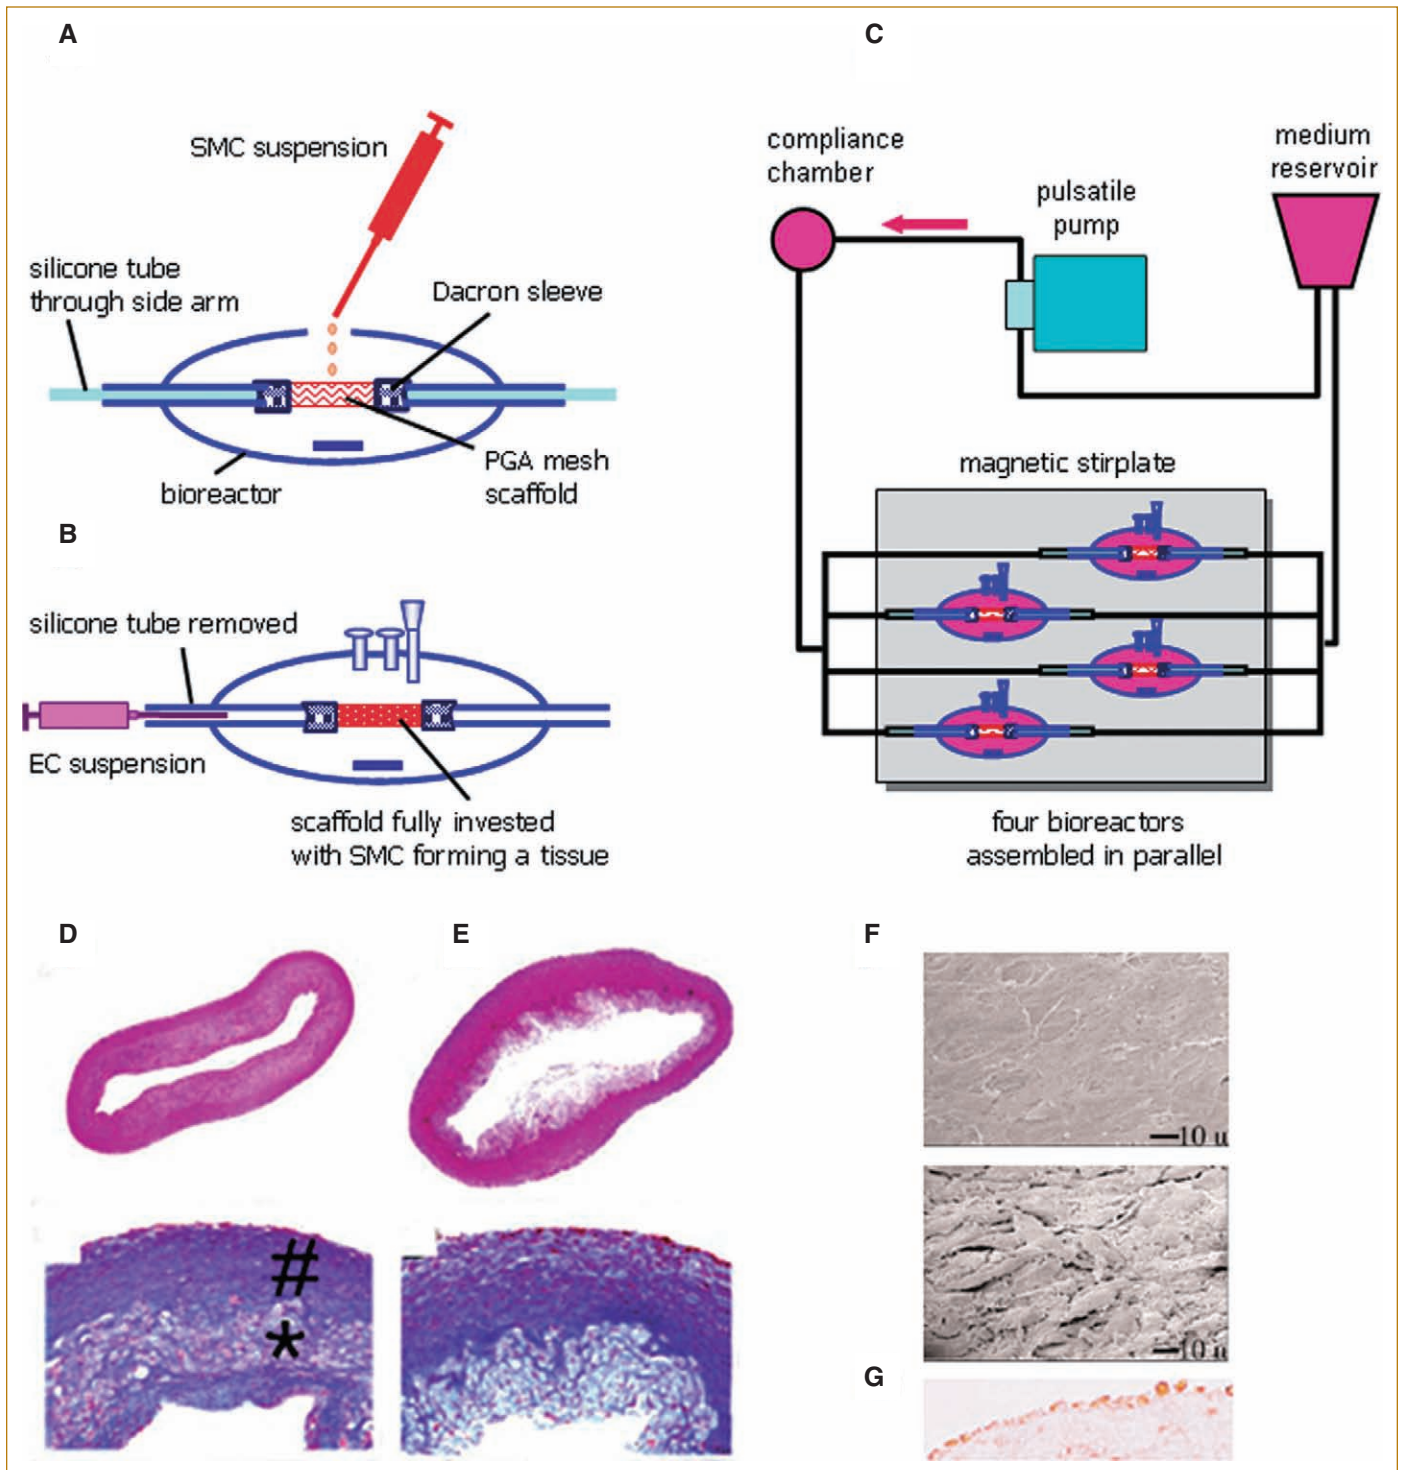

Arteries transport blood in the body under high pulsatile pressures (80–120 mmHg), inducing cyclic radial distensions ranging up to 10%. Arterial walls are composed of three layers: tunica interna, consisting of endothelial cells (EC); tunica media, consisting of smooth muscle cells (SMC) and connective tissue, comprising collagen and elastin fibers; and tunica externa, consisting of irregular connective tissue. Endothelium is exposed to blood flow and provides low thrombogenicity; tunica media provides strength, elasticity, and contractibility of blood vessels; while tunica externa provides support and attachment of the blood vessel to the surrounding tissue. Large-diameter arteries carrying high blood flow rates have been successfully replaced using synthetic grafts. However, synthetic grafts performed poorly when implanted to replace small-diameter arteries (<6 mm).

A biomimetic approach was developed to culture autologous tissue-engineered arteries using specialized scaffolds and bioreactors (Fig. 12.10) (Niklason, 1999; Niklason *et al.*, 1999; McKee *et al.*, 2003). Biodegradable PGA scaffolds (Prabhakar *et al.*, 2003) were chemically modified (Gao *et al.*, 1998) to enhance SMC attachment and sewn into tubes. Tubular scaffolds were placed over silicone tubing in bioreactors and seeded with SMC (Fig. 12.10A). After seeding, bioreactors were filled with culture medium that was supplemented by factors regulating vascular development, and a pulsatile flow was applied through the silicone tubing to

**FIG. 12.9.** Cultivation of tissue-engineered bone in perfusion bioreactors. **(A)** Schematic of single bioreactor compartment and perfusion flow diagram. (Data from Holtorf *et al.*, 2005.)

**FIG. 12.10.** Cultivation of engineered blood vessels in a bioreactor with pulsatile flow. *Cell seeding:* (A) Tubular PGA scaffolds were secured with polyester fiber (Dacron) sleeves to the bioreactor side openings, with silicone tubing protruding through the vessel lumen, and then seeded with SMCs by direct pipetting of concentrated cell suspension. (B) After cultivation period under pulsatile flow through the silicone tubing, the tubing was removed and EC suspension was injected into engineered vessel via side arm. (C) *Bioreactor system:* Each bioreactor was filled with culture medium that was supplemented by factors regulating vascular development and stirred with a magnetic stirrer; silicone tubing was connected to a perfusion system providing pulsatile radial stresses. Histological cross sections of engineered bovine vessels cultured for 8 weeks and stained with Verhoff's elastin stain (upper panels, original magnification  $\times 20$ ) and Masson's trichrome stain (lower panels, collagen stains blue; original magnification  $\times 100$ ): (D) engineered vessel cultured under pulsatile conditions, (E) control nonpulsed engineered vessel (# indicates the dense cellular region, \* indicates the region with undegraded polymer fibers). (Adapted from Niklason *et al.*, 1999.) (F) Scanning electron micrographs of luminal surfaces of nonendothelialized (upper) and engineered vessel seeded with ECs and perfused for 3 days in which a confluent EC layer can be observed (lower). Scale bar =  $10\ \mu\text{m}$ . (G) Platelet-endothelial cell adhesion molecule immunoperoxidase staining confirms EC identity on luminal surface. Original magnification:  $\times 200$ . (F and G adapted from Niklason *et al.*, 2001.)

mimic the flow of blood through developing blood vessels (Fig. 12.10B). In this way, cell-polymer constructs were subjected to pulsatile radial strains of 1.5–5% at a controlled frequency (165 bpm), for up to eight weeks. After eight weeks, the silicone tubing was removed, the EC suspension was injected into the lumen, and the flow rate was then gradually increased over three days of culture (Niklason *et al.*, 2001).

Using these approaches, arteries that are 3 mm in diameter and 8 cm in length have been cultured from bovine (Niklason *et al.*, 2001), porcine (Niklason *et al.*, 1999), and human cells (McKee *et al.*, 2003). Pulsatile flow enhanced the structure and mechanical integrity of engineered vessels as compared to nonpulsed vessels (Fig. 12.10C). Vessels engineered under pulsatile flow developed wall thickness of 200–400  $\mu\text{m}$  and rupture strengths greater than 2000 mmHg. Endothelium in engineered vessels was confluent and displayed multiple EC-specific markers (Fig. 12.10D). Engineered vessels remained patent for more than three weeks following implantation in miniature swine, but only if pre-cultured in the presence of pulsatile radial stress.

#### Example 7. “Smart Well Plates” for Screening and Directed Differentiation of Cells

The clinical utility of cell-based therapies depends on simple, robust methods to select and expand the cells, to precisely regulate their differentiation into specific phenotype(s), and to fully characterize their potential for tissue repair. Ideally, the properties of cells should be tailored for a specific application and a specific patient. This is particularly true for human stem cells (embryonic and adult) and their use in clinical settings, due to the strong and complex dependence of cell responses on exogenous factors.

At this time, there are two distinctly different complementary approaches to cell cultivation in a clinical setting of stem cells: well-plate cultures and bioreactor cultures. The use of conventional *well plates* is still most widely spread (both in research labs and clinically) because of their simplicity and well-established experimental protocols. The key disadvantage of well plates is the inability to control some of the key regulatory factors of stem cell function, most notably (a) hydrodynamic shear, and (b) oxygen levels. The use of *bioreactors* involving convective mixing and/or perfusion of culture medium enables precise control of the cellular microenvironment, a feature that can substantially advance the repertoire of regulatory regimes we can use to modulate cell function. Unfortunately, bioreactors are in most cases larger in volume than well plates, and their use requires some technical skill. Most notably, the use of bioreactors involves the change from tissue culture plastics to other, less preferred substrates (such as glass and either natural and synthetic polymers). At present, a researcher can only choose between well plates and bioreactors, i.e., between routinely used protocols and precise

control of environmental factors. Clearly, this is a significant trade-off that limits the cell outcomes.

The importance of hydrodynamic shear for the maturation and differentiation of stem cells has raised interest in using microfluidic devices, which again involve the need to switch to a substrate different from the tissue culture plastics (Leclerc *et al.*, 2004; Shin *et al.*, 2004; B. L. Gray *et al.*, 2002). Also, there are various problems with cell seeding and attachment within microfluidic devices. In this respect, microfluidic devices are not necessarily user friendly.

One recently developed system, smart well plates, combines the advantages of well plates and bioreactors within a single, user-friendly device. The smart well plates (SWP) add functionality to the conventional well plate while retaining its inherent simplicity. The clinician preparing cells can simply replace the well plate cover with the SWP, to get the capability to apply medium flow and to control hydrodynamic shear, oxygen and pH, and medium supplements. The cover is designed and built to fit over a standard six-well plate (Fig. 12.11) and contains six plungers ( $\varnothing$  35 mm) extended into each well and precisely machined to provide a defined shear stress to the cells. A multichannel peristaltic pump is used to drive medium across the lower surface of each piston, up through the center, and back to each well. A gas exchanger is not required if the device is in an incubator, but one can be used if studies under low and high oxygen levels are conducted. The plungers and cover are constructed of clear polycarbonate to allow direct microscope observation of the cells.

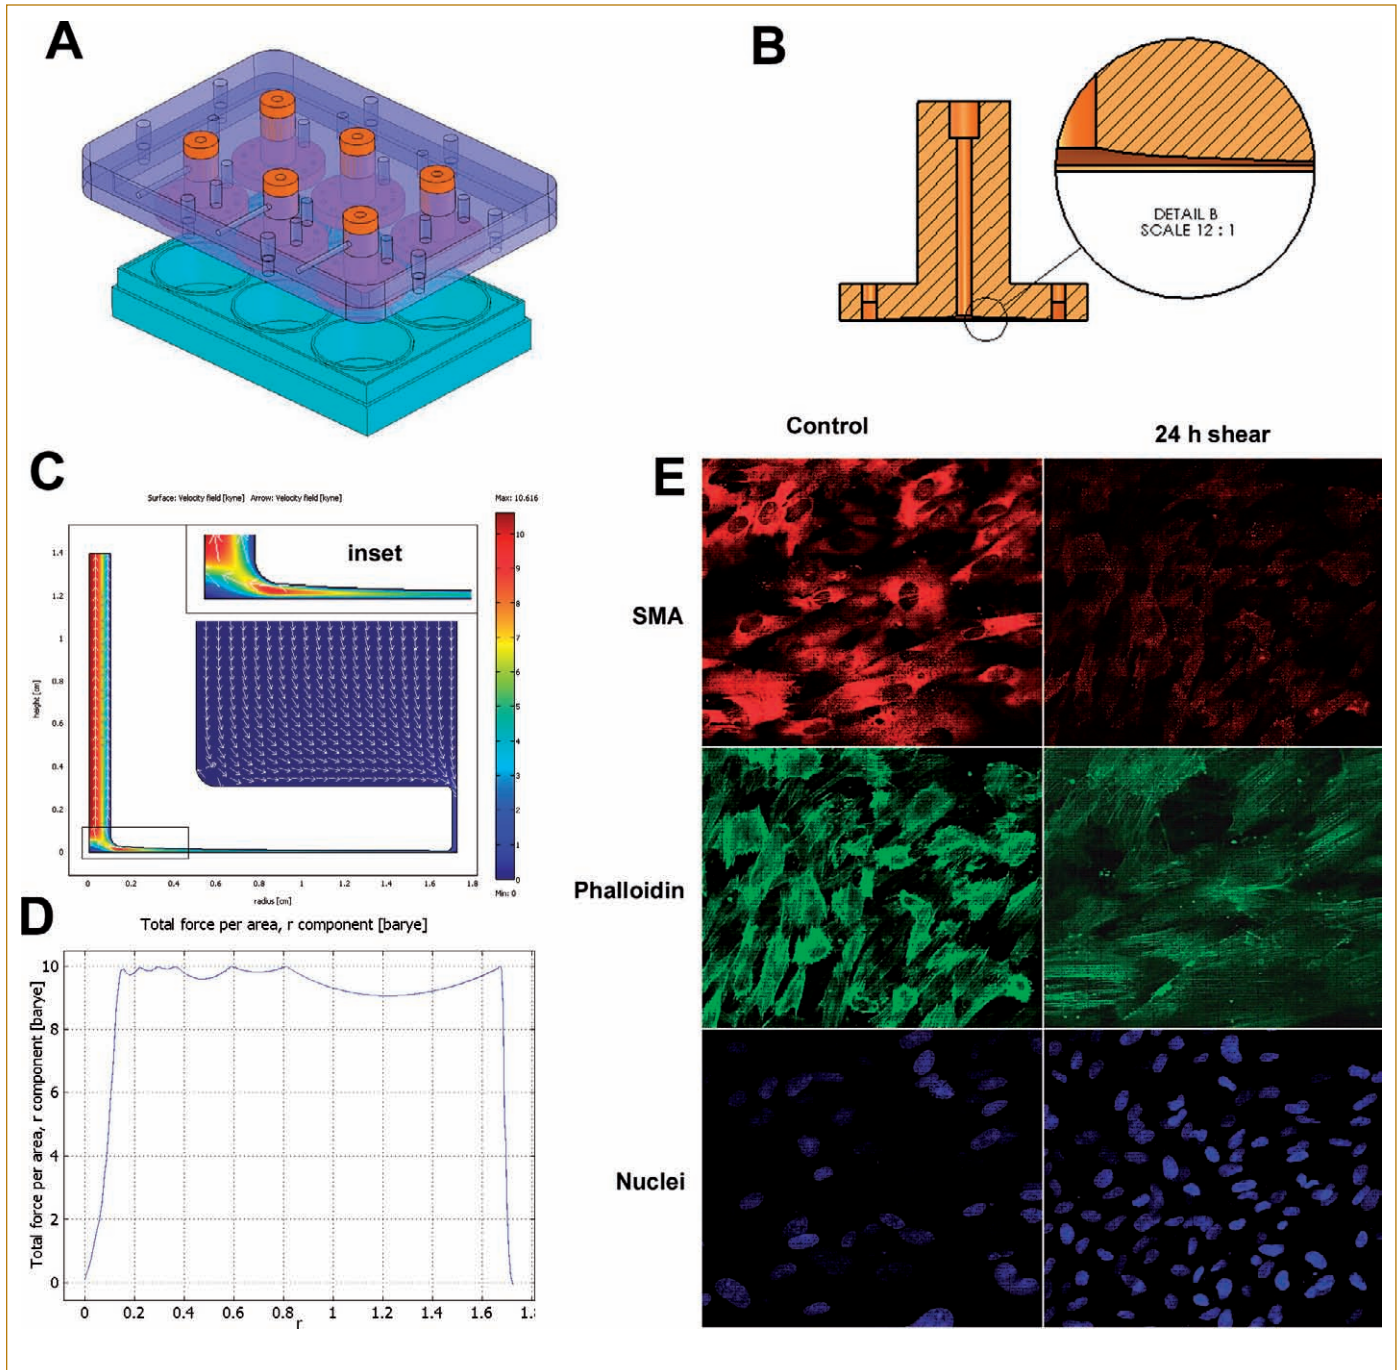

One example of application of this device is the modulation of vascular differentiation of human embryonic stem cells (hESC). Vascular smooth muscle cells (v-SMC) were derived in this device using our previously developed protocols (Gerecht-Nir *et al.*, 2003), under continuous hydrodynamic shear stress for 24 hours. Cells adopted characteristic perpendicular orientation to the direction of shear, and they had enhanced expression of  $\alpha\text{SMA}$  (Fig. 12.11), suggesting that shear stress enhanced the expression and maturation of the vascular phenotype. Shear stress also affected the organization of stress fibers, thus enhancing the functionality of hES-derived v-SMCs.

Other applications include cell screening and directed differentiation for a wide variety of cell therapies. In all cases, the outcome of the clinical cell-based therapy depends on the quality of cell preparation, which in turn depends on control of environmental factors during cell cultivation. Some of the important factors are listed in Table 12.5, which explains briefly how they can be manipulated in SWPs.

#### Example 8. Engineered Cardiac Muscle: Electrical Stimulation

The contractile apparatus of cardiac myocytes consists of sarcomeres, with high density of mitochondria supporting high metabolic activity and electrical signal propagation provided by specialized intercellular connections, gap

**FIG. 12.11.** Multiwell device with controlled application of hydrodynamic shear. **(A)** Custom cover placed over a standard six-well plate contains plungers designed to provide well-defined levels of hydrodynamic shear at cell monolayers in completely independent culture wells. **(B)** Section view of the plunger. Culture medium enters through the center of the plunger. **(C, D)** The curvature of the plunger is designed to maintain constant hydrodynamic shear at all radial positions in the well. **(E)** Modulation of vascular differentiation of human embryonic stem cells (hESC) by hydrodynamic shear. The application of shear stress during cultivation markedly enhanced the expression and organization of  $\alpha$ -SMA (red) and phalloidin (green). Nuclei are shown in blue.

**Table 12.5.** Examples of applications of “smart well plates” for optimizing cell culture parameters

**Shear stress.** Device can be used for rapid screening under either constant or radially changing shear.

**Growth factors.** The plunger can be coated with growth factors that will diffuse slowly into the culture medium. Plungers can be exchanged throughout an experiment to direct cell development.

**Cell coculture.** The plunger surface can be coated with adhesion factors, seeded with one type of cells, and placed into the well plate in close proximity to a second type of cells already in the well plate.

**Hypoxia.** A controlled gas environment can be achieved by integrating a gas exchanger into the perfusion loop. Optical pH and pO<sub>2</sub> sensors can be used for on-line monitoring and control.

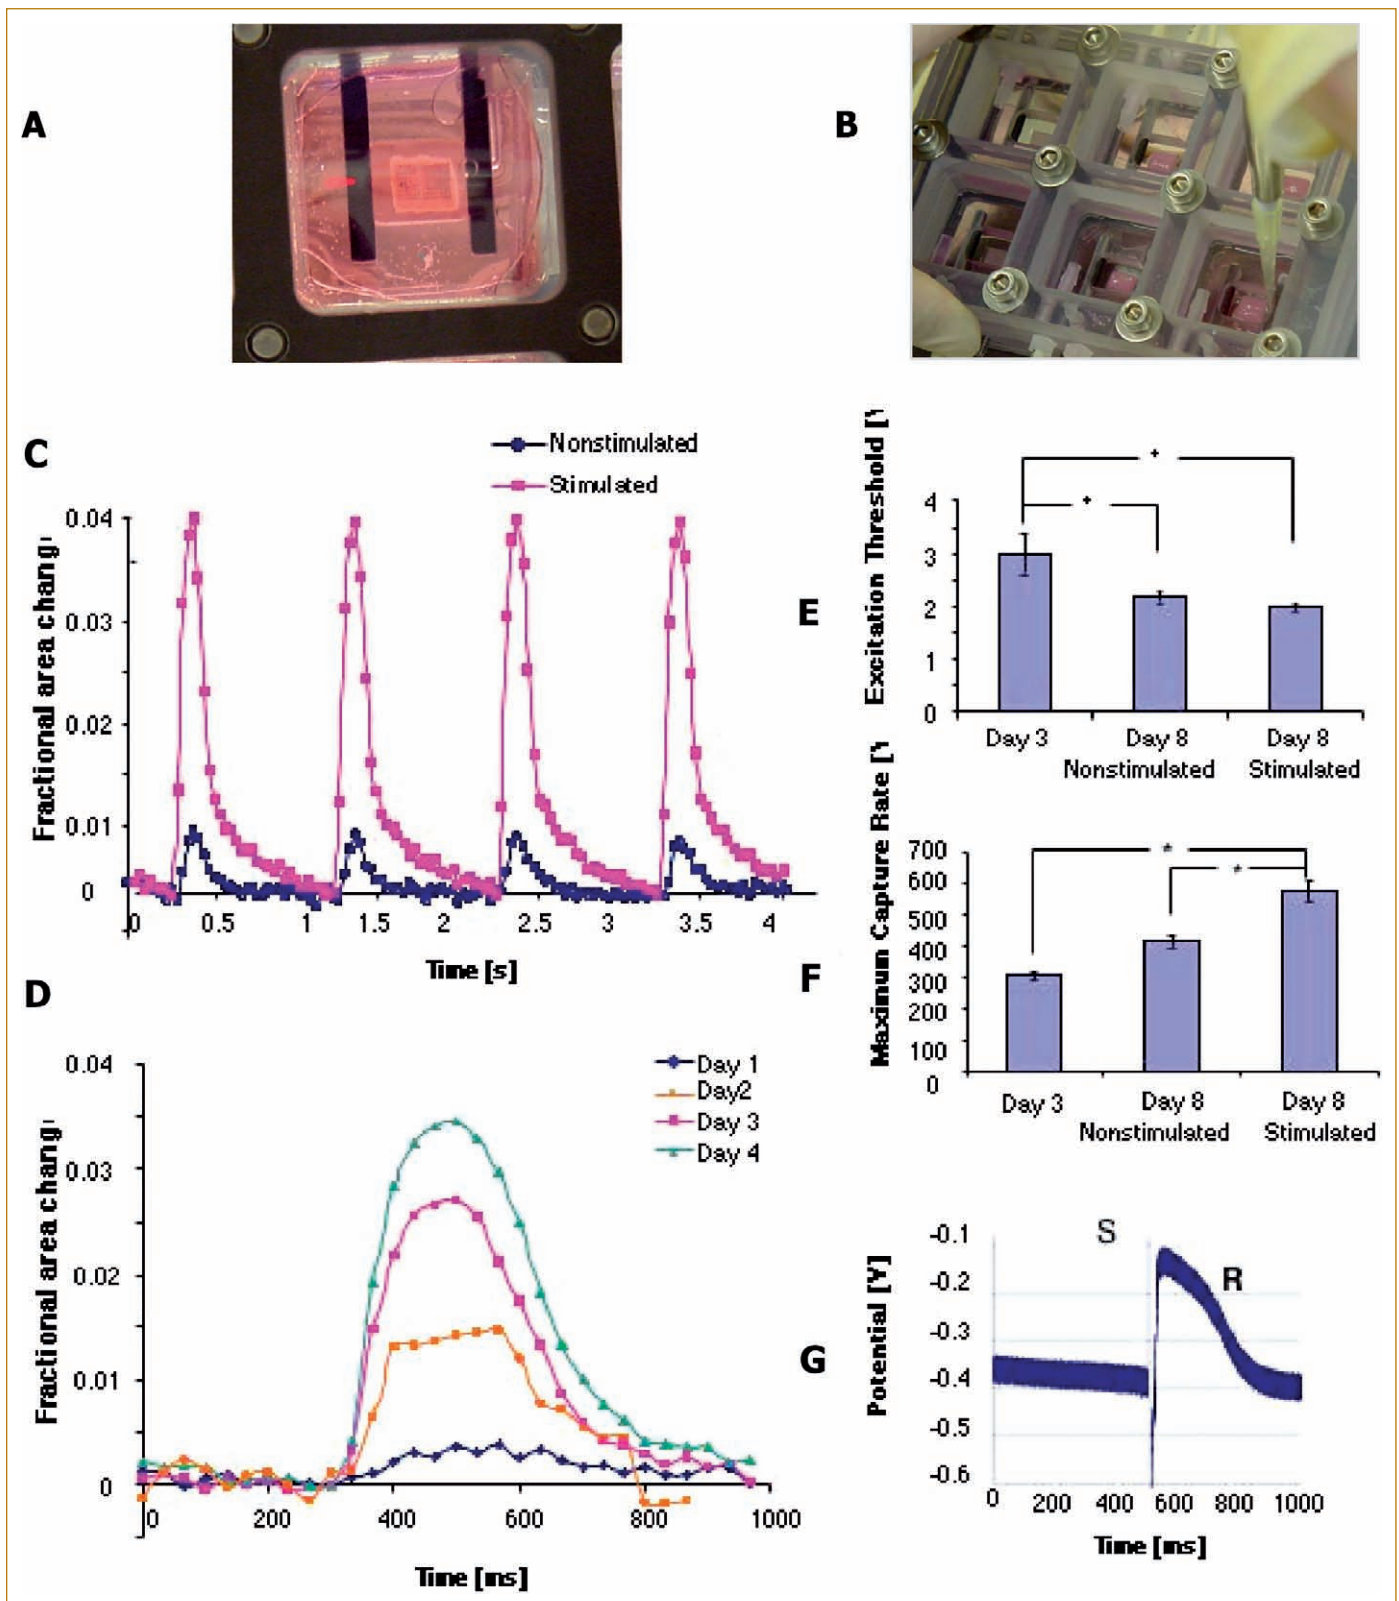

junctions (MacKenna *et al.*, 1994; Brilla *et al.*, 1995). The control of heart contractions is self-contained and can be attributed to the groups of specialized cardiac myocytes (pace makers), the fastest of which are located in the sinoatrial node. Contraction of the cardiac muscle is driven by the waves of electrical excitation generated by pacing cells that spread rapidly along the membranes of adjoining cardiac myocytes and trigger release of calcium, which in turn stimulates contraction of the myofibrils. Electromechanical coupling of the myocytes is crucial for their synchronous response to electrical pacing signals (Severs, 2000). Notably, the cardiovascular system is the first organ system that develops in the body.

To enhance the differentiation of cultured cardiac myocytes and their functional assembly into engineered cardiac constructs, cardiac-like electrical stimuli were applied to induce contractions of cultured constructs. The stimulation chamber was designed by fitting a petri dish with two stimulating electrodes connected to a commercial cardiac stimulator (Fig. 12.12) (Radisic *et al.*, 2003). Constructs were stimulated using suprathreshold square biphasic pulses (2-ms duration, 1 Hz, 5 V), and the stimulation was initiated after one to five days of scaffold seeding and applied for up to eight days. Immunohistochemical staining and contractile responses indicated that the stimulation should be initiated three days after seeding, a period that appeared to be sufficient for the cells to recover from isolation and attach to the scaffolds.

Cardiac constructs stimulated during cultivation had significantly better contractile responses to pacing as compared to unstimulated controls. The measured amplitude of synchronous contractions was on average seven times

higher in the stimulated than nonstimulated group (Fig. 12.12C), and it progressively increased with time in culture (Fig. 12.12D). Excitation threshold (ET), defined as the minimum amplitude of stimulation at 60 bpm necessary to observe synchronous beating of the entire construct, was lower for stimulated than nonstimulated constructs (Fig. 12.12E). Consistently, the maximum capture rate was significantly higher for stimulated than for nonstimulated constructs (Fig. 12.12F). Excitation–contraction coupling of CM in stimulated constructs was also evidenced by recording the electrical activity using a platinum electrode positioned ~2 mm away from the pair of stimulating electrodes. The shape, amplitude (~100 mV), and duration (~200 ms) of electrical potentials recorded for cells in constructs that were electrically stimulated during culture (Fig. 12.12) were similar to those reported previously for cells from mechanically stimulated constructs (Zimmermann *et al.*, 2002). Importantly, the improved contractile properties were not the result of increased cellularity.

Stimulated constructs exhibited higher levels of  $\alpha$ -myosin heavy-chain ( $\alpha$ -MHC), connexin 43, creatin kinase-MM, and cardiac troponin I expression as assessed from Western blots and compared to unstimulated constructs. The ratio of  $\alpha$ -MHC (adult) and  $\beta$ -MHC (neonatal) isoforms (~1.5 at day 3) decreased to 1.4 in the nonstimulated group and increased to 1.8 in the stimulated group by the end of the cultivation period, indicating cell maturation in the stimulated group. Stimulated constructs had thick, aligned myofibers that expressed sarcomeric  $\alpha$ -actin, troponin I,  $\alpha$ -MHC and  $\beta$ -MHC resembling myofibers in the native heart, and elongated nuclei. Stimulated constructs also exhibited stronger staining for connexin-43 than either early or

**FIG. 12.12.** Cardiac tissue engineering with electrical stimulation. **(A, B)** *Experimental setup*: Multiple culture wells are fitted with stimulating electrodes. Cardiac constructs prepared by seeding collagen sponges ( $6 \times 8 \times 1.5$  mm) with neonatal rat ventricular cells ( $5 \times 10^6$ ) were stimulated using suprathreshold square biphasic pulses (2 ms in duration, 1 Hz, 5 V) starting at day 3 of culture, up to day 8 of culture. **(C)** Contraction amplitude of constructs cultured for a total of 8 days, shown as a fractional change in the construct size. Electrical stimulation increased the amplitude of contractions by a factor of 7. **(D)** Amplitude of contractions progressively developed with time in culture and was associated with transmembrane potentials similar to action potential measured in native cardiac myocytes. **(E)** Excitation threshold (ET) decreased and **(F)** maximum capture rate (MCR) increased significantly both with time in culture and due to electrical stimulation. (\*) denotes statistically significant differences ( $p < 0.05$ ;  $n = 5-10$ ). **(G)** Contractile activity was associated with the propagation of action potentials. (C–G reproduced with permission from Radisic *et al.*, 2004.)

nonstimulated constructs. In contrast, early and nonstimulated constructs exhibited a lower level of tissue organization and contained round nuclei.

Cells and nuclei in stimulated constructs were elongated and exhibited specialized cytoplasmic features characteristic of native myocardium. Gap junctions, intercalated discs, and microtubules were all more frequent in the stimulated than in the nonstimulated group and qualitatively more similar to those of neonatal rat heart. Cells in stimulated constructs contained aligned myofibrils and well-developed sarcomeres with clearly visible M, Z lines, H, I, and A bands. In most cells, Z lines were aligned, and the intercalated discs were positioned between two Z lines. Mitochondria (between myofibrils) and abundant glycogen were detected. In contrast, nonstimulated constructs had poorly developed cardiac-specific organelles and poor organization of ultrastructural features.

Overall, cardiac-like electrical stimulation during *in vitro* tissue culture progressively enhanced the excitation-contraction coupling and improved the properties of engineered myocardium at the cellular, ultrastructural, and tissue levels.

## V. ACKNOWLEDGMENTS

Bioreactor designs described in this chapter and their application to tissue engineering are a result of a meritorious, long-term effort of many different research groups, and the individual contributions are specifically credited. The senior

## IV. SUMMARY

Much progress has been made in the design of advanced bioreactors, based on our improved understanding of the conditions required for directing cell differentiation and assembly into functional tissue structures. Most of the published work has been based on the use of animal cells or nonstandardized human cell populations. One major challenge ahead of us is to extend the application of technologically advanced, biologically inspired tissue-engineering systems to the cultivation of functional human tissue grafts, using clinically suitable cell sources. Another challenge is to further advance the capabilities of our *in vitro* culture systems. The growing interactions between the fields of tissue engineering and developmental biology are expected to facilitate further the translation of biological principles into our engineering designs. The application of engineered tissues in regenerative medicine will also require the demonstration of their safety and efficacy in rigorous animal models. Many current efforts are directed at moving the science and practice of tissue engineering from observational to mechanistic and rational and from the limited current products to many more that will improve people's lives.

author is grateful to the NIH (NIDCR, NHLBI, NIBIB) for supporting the tissue-engineering work in her laboratory. The authors thank Sue Kangiser for her help in the preparation of the manuscript.

### I. INTRODUCTION

The extracellular milieu is critical for the control of the behavior of every cell in all tissues. Many factors can contribute to the environment of a cell, for example, cell : cell contact, growth factors, extracellular matrix (ECM) proteins, and matricellular proteins. All of these components act together to regulate cell surface protein activity, intracellular signal transduction, and subsequent gene expression, which leads to proliferation, migration, differentiation, and ultimately the formation of complex tissues. This chapter focuses on matricellular proteins as modulators of extracellular signals. The matricellular proteins are characterized as secreted, modular proteins that are associated with the extracellular matrix but do not act as structural constituents (Bornstein and Sage, 2002). Presumably, the function of matricellular proteins is to provide a link between the extracellular matrix and cell surface receptors or between cytokines and proteases localized in the extracellular environment whose activity might be affected by this interaction (Bornstein and Sage, 2002). Thrombospondin 1 and 2, tenascin-C, osteopontin, and SPARC are representatives of this class of proteins. A growing body of evidence points to these proteins as important mediators of growth factor, ECM, and cell signaling pathways (Table 13.1). Consequently, *in vitro*

systems designed to mimic tissue conditions should consider the influence of matricellular proteins.

### II. THROMBOSPONDIN-1

Thrombospondin-1 is a 450,000-dalton glycoprotein with seven modular domains (Bornstein, 2001). To date, five different paralogs of thrombospondin have been identified, termed thrombospondins 1–5. This chapter reviews the two more characterized forms, thrombospondin-1 and thrombospondin-2. At least five different ECM-associated proteins are able to bind to thrombospondin-1: collagens I and V, fibronectin, laminin, fibrinogen, and SPARC (Bornstein, 2001). Likewise, cell surface receptors for thrombospondin are multiple and include the integrin family of extracellular matrix receptors (Bornstein, 2001). Given the significant number and variety of thrombospondin-1-binding proteins, it is of little surprise that a wide variety of functions has been attributed to this protein, some of which appear to be contradictory. Many of these disparities may, however, actually reflect the dynamic interaction of thrombospondin-1 with other extracellular factors that can influence cells in different ways to give rise to distinct cellular outcomes—a common theme in matricellular protein biology.

**Table 13.1.** Matricellular protein interactions and activities

A summary of the activities for the matricellular proteins described in this chapter. This table is not a complete list of all activities and receptors for the proteins included in the table nor are all the matricellular proteins included. For references refer to the text.

*Abbreviations:* Col: collagen; Fn: fibronectin; Ln, laminin; Fg: fibrinogen. Growth factor abbreviations are defined in the text.

Several studies have established an antiangiogenic function of thrombospondin-1 (Armstrong and Bornstein, 2003). *In vitro*, aortic endothelial cells transfected with antisense thrombospondin-1 cDNA generate twice as many capillary-like structures on a gelled basement membrane than control cells that produce higher levels of thrombospondin-1 (DiPietro *et al.*, 1994). *In vivo*, increased expression of thrombospondin-1 by tumor cells results in decreased vascularization and an accompanied reduction in tumor progression by a number of different types of tumor-derived cells (de Fraipoint *et al.*, 2001).

One mechanism by which thrombospondin-1 might influence angiogenesis is by promoting cell death in microvascular endothelial cells (Jimenez *et al.*, 2000). CD-36, a thrombospondin-1 cell surface receptor, has been shown to be required for caspase-3-mediated induction of apoptosis by thrombospondin-1. Antimigratory effects elicited by CD-36 interaction with thrombospondin-1 in endothelial cells has also been demonstrated. As the first natural inhibitor of angiogenesis, characterization of the mechanisms by which thrombospondin-1 functions has provided valuable insight into strategies to control blood vessel formation.

Thrombospondin-1, like many of the matricellular proteins, influences cytokine activity. For example, thrombospondin-1 has been shown to interact specifically with transforming growth factor (TGF- $\beta$ ) (Schultz-Cherry and Murphy-Ullrich, 1993). This interaction leads to activation of the latent form of TGF- $\beta$ , presumably through a conformational change in the cytokine, which allows interaction with cell surface receptors (Schultz-Cherry and Murphy-

Ullrich, 1993). Consequently, the presence of thrombospondin-1 in the extracellular milieu might affect the activity of this potent, multifunctional cytokine. Generation of a thrombospondin-1-null mouse lends support to the importance of thrombospondin-1-mediated activation of TGF- $\beta$  *in vivo*. The phenotype in the absence of thrombospondin-1 expression mimics to some degree the phenotype of the TGF- $\beta$ -null mouse (Crawford *et al.*, 1998). Specifically, similar pathologies of the lung and pancreas are observed in both mice, and, importantly, thrombospondin-1-null mice treated with thrombospondin-1 peptides show a partial restoration of active TGF- $\beta$  levels and a reversion of the lung and pancreatic abnormalities toward tissues of wild-type mice. Importantly, thrombospondin-1 is a potent chemoattractant for inflammatory cells (Bornstein, 2001). Therefore, a reduction in active TGF- $\beta$  levels in thrombospondin-1-null mice might be influenced by inflammatory cell recruitment.

Thrombospondin-1 influences cell adhesion and cell shape. For example, it will diminish the number of focal adhesions of bovine aortic endothelial cells and thus will promote a migratory phenotype (Murphy-Ullrich, 2001). Thrombospondin-1, therefore, is proposed to modulate cell : matrix interaction to allow for cell migration when necessary. An intermediate stage of adhesion describes cell responses to counteradhesive matricellular proteins and, as such, are predicted to promote cell motility (Murphy-Ullrich, 2001). Accordingly, thrombospondin-1 expression is observed during events such as dermal wound repair, when cell movement is required. Thrombospondin-1 is also

expressed by many tumor cells and might facilitate metastatic migration (Tuszynski and Nicosia, 1996). In fact, metastatic human carcinoma cells transfected with antisense thrombospondin-1 cDNA to reduce thrombospondin-1 protein expression lose their capacity to proliferate and metastasize in athymic mice (Castle *et al.*, 1991).

### III. THROMBOSPONDIN-2

Similar to thrombospondin-1, thrombospondin-2 inhibits angiogenesis *in vivo*. Recombinant thrombospondin-2 contained in pellets implanted in the rat cornea inhibits basic-fibroblast growth factor (bFGF)-induced vessel invasion to nearly the same degree as thrombospondin-1 (Volpert *et al.*, 1995). Thus, the observation that the thrombospondin-2-null mouse appears to have a greater degree of vascularization in the skin is in accordance with the hypothesis that thrombospondin-2 might serve as an endogenous regulator of angiogenesis in mice (Kyriakides *et al.*, 1998). In fact, the expression pattern of thrombospondin-2 is more consistent with the importance of this protein in vascular formation, because the mRNA for thrombospondin-2 is more closely associated with the vasculature in developing tissues than that of thrombospondin-1 (Armstrong and Bornstein, 2003).

How might thrombospondin-2 mediate inhibition of angiogenesis? Abrogation of thrombospondin-2 expression results in increased amounts of matrix metalloproteinase (MMP)-2 activity (Yang *et al.*, 2000). Thrombospondin-2 binds to MMP-2 and facilitates uptake by scavenger receptors on cell surfaces (Yang *et al.*, 2001). Hence without thrombospondin-2, MMP-2 levels accumulate in the extracellular milieu and result in significant decreases in cell adhesion. The increase in MMP-2 levels is correlated with decreased amounts of tissue transglutaminase on thrombospondin-2-null cell surfaces (Agah *et al.*, 2005). Because transglutaminase is known to enhance integrin-mediated cell attachment and serve as a substrate of MMP-2, the increase in MMP-2 activity is proposed to elicit decreased cell adhesion in the absence of thrombospondin-2 by diminishment of the amounts of transglutaminase on cell surfaces. Hence, blood vessel formation appears to be sensitive to levels of MMP-2 in tissues. Likewise, tissue transglutaminase on cell surfaces might also contribute to angiogenesis.

Another observation from the thrombospondin-2-null mouse is that of altered collagen fibrillogenesis in the skin, relative to that seen in wild-type mice. The collagen fibrils in the null mice are larger in diameter, have aberrant contours, and are disordered (Kyriakides *et al.*, 1998). Presumably this effect on collagen fibril formation contributes to the reduced tensile strength of the skin in thrombospondin-2-null versus wild-type mice. An intriguing relationship between aberrant collagen fibril morphology and decreased transglutaminase activity is suggested by the thrombospondin-2-null phenotype.

Thrombospondins-1 and -2 can act as negative regulators of cell growth. In particular, endothelial cells are susceptible to an inhibition of proliferation by both proteins, resulting in their classification as inhibitors of angiogenesis (Armstrong and Bornstein, 2003). However, the variety of cell surface receptors for thrombospondins allows for diverse signaling events in different cell types; consequently, there might be situations when thrombospondin appears to support angiogenesis as well (Nicosia and Tuszynski, 1994). Thrombospondin-1 has been shown to modulate the activity of at least two cytokines, TGF- $\beta$  and hepatocyte growth factor (HGF): diminished activity, in the case of HGF, or enhanced activity, as seen for TGF- $\beta$ . Finally, thrombospondin-1 can alter cell shape to promote a migratory phenotype but can also inhibit migration. Such conflicting conclusions illustrate the importance of contextual presentation of matricellular proteins in various assays. Further characterization of the thrombospondins, including closer examination of the remaining family members (thrombospondins 3–5), will no doubt yield fascinating insight into this multifunctional gene family.

### IV. TENASCIN-C

Tenascin-C is a matricellular protein with a widespread pattern of developmental expression, in comparison to a restricted pattern in adult tissues. In addition to tenascin-C, three other, less characterized forms of tenascin have been identified: tenascin-R, tenascin-X, and tenascin-W (Chiquet-Ehrismann, 2004). This review focuses on tenascin-C, as the best characterized of the tenascin gene family. Tenascin-C consists of six subunits (or arms) linked by disulfide bonds to form a 2000-kDa molecule that can associate with fibronectin in the extracellular matrix (Hsai and Schwarzbauer, 2005). Like thrombospondin-1, a number of different functions have been attributed to tenascin-C, and, accordingly, a number of cell surface receptors appear to mediate distinct properties of this matricellular protein. At least five different integrins are known receptors for tenascin-C, as well as annexin II (Crossin, 1996). Whereas the integrins appear to support cell adhesion to tenascin-C, annexin II is thought to mediate the counteradhesive function attributed to this protein. Hence, tenascin-C can act as either an adhesive or a counteradhesive substrate for different cell types, dependent on the profile of receptors expressed on the cell surface (Crossin, 1996).

Tenascin-C has also been shown to modulate the activity of growth factors. Specifically, it promotes epidermal growth factor (EGF)-dependent and bFGF-dependent cell growth (End *et al.*, 1992; Jones *et al.*, 1997). In fact, Jones *et al.* (1997) have shown that smooth muscle cells plated in a collagen gel secrete MMPs that degrade the collagen to expose integrin receptor-binding sites. Engagement of these receptors induces tenascin-C expression; tenascin-C is subsequently deposited into the extracellular matrix and can itself serve as an integrin ligand. The deposition of tenascin-

C leads to cell shape changes initiated by a redistribution of focal adhesion complexes concomitant with a clustering of EGF receptors on the cell surface. Presumably, clustering of the EGF receptors facilitates EGF signaling and thereby enhances the mitogenic effect of EGF. Conversely, when MMP activity is inhibited, tenascin-C expression is decreased and the cells become apoptotic (Jones *et al.*, 1997). Thus, tenascin-C is able to modulate EGF activity such that the presence of this matricellular protein supports cell growth and its absence induces programmed cell death.

Given the widespread expression of tenascin-C in the developing embryo, the lack of an overt phenotype in the tenascin-C-null mouse is surprising (Chiquet-Ehrismann and Tucker, 2004). In particular, the high level of tenascin-C expression in the central and peripheral nervous systems had indicated that the absence of this protein might lead to neuronal abnormalities. Although no histological differences could be detected in the brains of adult tenascin-C-null mice, they displayed behavioral aberrations, including reduced anxiety and enhanced novelty-induced activity (Steindler *et al.*, 1995; Morellini and Schachner, 2006). In addition, altered numbers of embryonic central nervous system stem cells were noted in the absence of tenascin-C expression, an observation confirming that the composition of the extracellular matrix is an important factor in cell differentiation (Garcion *et al.*, 2004).

The genetic background of the tenascin-C-null mouse is likely to be a major factor in the identification of tissues in which tenascin-C might be functionally important. For example, Nakao *et al.* (1998) used three different congenic mouse lines to study the effect of Habu-snake venom-induced glomerulonephritis in a tenascin-C-null background. Although the disease is worse in all tenascin-C-null mice than in wild-type controls, each line exhibits a different level of severity. Induction of the disease in one strain, GRS/A, results in death from irreversible renal failure (Nakao *et al.*, 1998). Moreover, mesangial cells cultured from tenascin-C-null animals do not respond to cytokines such as platelet-derived growth factor (PDGF) unless exogenous tenascin-C is included in the culture medium (Nakao *et al.*, 1998). Hence, tenascin-C can also modulate the activity of this growth factor, as observed previously for EGF. Tenascin-C provides another example of a matricellular protein able to affect growth factor efficacy.

Although tenascin-C shows a limited pattern of expression in the adult, an induction of tenascin-C is seen in many tissues undergoing wound repair or neoplasia (Chiquet-Ehrismann and Tucker, 2004). Thus tenascin-C, like the other matricellular proteins, is ideally suited to act as a modulator of cell shape, migration, and growth. One mechanism by which tenascin-C influences cell behavior is through the modulation of fibronectin interaction with cells. Tenascin-C decreases cell adhesion to fibronectin through competition with a heparan sulfate proteoglycan, syndecan 4 (Midwood *et al.*, 2004). Syndecan 4 is required for efficient

cell attachment to fibronectin and for tenascin-C inhibition of adhesion to fibronectin. Hence, a scenario in which tenascin-C competes for syndecan 4 binding to fibronectin is consistent with these results.

The paucity of developmental abnormalities manifested in the tenascin-C-null mouse points to the greater importance of tenascin-C in remodeling events that take place in response to injury or transformation. For example, tenascin-C has been shown to regulate cardiac neovascularization by bone marrow-derived endothelial progenitor cells in response to angiogenic stimuli in adult mice (Ballard *et al.*, 2006). In addition, high levels of tenascin-C expression are frequently associated with several types of malignancies including tumors of the brain (Chiquet-Ehrismann and Tucker, 2004).

## V. OSTEOPONTIN

As the name implies, osteopontin was originally classified as a bone protein. A more thorough examination, however, reveals a widespread expression pattern for this protein, with multiple potential functions (Rangaswami *et al.*, 2006). Osteopontin associates with the extracellular matrix, for it binds to fibronectin and to collagens I, II, III, IV, and V. Osteopontin also affects cellular signaling pathways by virtue of its capacity to act as a ligand for multiple integrin receptors as well as cluster designation (CD)-44 (Rangaswami *et al.*, 2006). Thus osteopontin, like most of the matricellular proteins, is able to act as a bridge between the extracellular matrix and the cell surface. Since matricellular proteins might be synthesized, secreted, and incorporated into the extracellular matrix with greater ease than more complex secreted proteins, which must be incorporated into fibrils and assembled into a network, a bridging function might be useful during remodeling events in the organism when rapid conversion of the cellular substrata is required for cell movement.

In support of this concept, Weintraub *et al.* (1996) report that transfection of vascular smooth muscle cells with anti-osteopontin cDNA reduces adhesion, spreading, and invasion of three-dimensional collagen matrices. Addition of osteopontin to the collagen gel restores the capacity of these cells to invade the gel. Osteopontin also appears to be susceptible to modification by extracellular proteases, which have revealed cryptic integrin-binding sites within the sequence. The protease thrombin cleaves osteopontin at the N-terminal domain and exposes binding sites for integrin  $\alpha 9 \beta 1$  and  $\alpha 4 \beta 1$  (Smith *et al.*, 1996). In addition, Senger *et al.* (1996) report that endothelial cells treated with vascular endothelial growth factor (VEGF) increase their expression of the integrin  $\alpha v \beta 3$ , another osteopontin cell surface receptor, concomitantly with an increase in osteopontin. These investigators also show an increase in the amount of thrombin-processed osteopontin in tissues injected with VEGF and radiolabeled osteopontin. The significance of this result lies in the enhanced support of endothelial cell migra-

tion *in vitro* by thrombin-cleaved versus full-length protein. Since the migratory activity of the endothelial cells is blocked partially by an anti- $\alpha v \beta 3$  antibody, the remainder of the activity might be attributed to  $\beta 1$ -integrins or to other cell surface receptors (Senger *et al.*, 1996).

The capacity of osteopontin to influence cell migration might be linked to matrix metalloproteinase activity. Osteopontin is a member of the recently classified SIBLING (small integrin-binding ligand N-linked glycoprotein) family of proteins (Fisher and Fedarko, 2003), which have been shown to bind to and regulate the activity of MMPs. Osteopontin binds to recombinant proMMP-3 and active MMP-3 (Fedarko *et al.*, 2004). In addition, a decrease in MMP-9 activity has been reported in osteopontin-null myofibroblasts and vascular smooth muscle cells (Lai *et al.*, 2006).

The promotion of cell survival is another property ascribed to osteopontin. Denhardt and Noda (1998) have reported that human umbilical vein endothelial cells plated in the absence of growth factors will undergo apoptosis. If these cells are plated on an osteopontin substrate, however, apoptosis is inhibited. Furthermore, rat aortic endothelial cells subjected to serum withdrawal undergo programmed cell death, a response inhibited by an osteopontin substrate. In fact, it is the ligation of integrin  $\alpha v \beta 3$  by osteopontin at the cell surface that induces nuclear factor-kappa B (NF- $\kappa$ B), a transcription factor that controls a variety of genes through direct binding to their promoters. Thus osteopontin and other  $\alpha v \beta 3$  ligands can protect cells from apoptosis (Scatena *et al.*, 1998).

Osteopontin is involved in inflammatory responses. Expression of osteopontin is found to increase during intradermal macrophage infiltration, and purified osteopontin injected into the rat dermis leads to an increase in the number of macrophages at the site of administration. Importantly, antiosteopontin antibodies inhibit macrophage accumulation in a rat intradermal model after a potent macrophage chemotactic peptide is used to induce an inflammatory response (Giachelli *et al.*, 1998). Osteopontin expression is required for development of an effective  $T_H1$  immune response (Ashkar *et al.*, 2000). Interestingly, a recently described intracellular form of osteopontin has been implicated as the mediator of interferon- $\alpha$  production in plasmacytoid dendritic cells (Shinohara *et al.*, 2006).

The phenotype of the osteopontin-null mouse supports the hypothesis that osteopontin affects macrophage activity. Although the number of macrophages does not appear to differ significantly in incisional wounds of wild-type and osteopontin-null mice, the amount of cell debris was higher in wounds of the latter animals. Because macrophages are thought to be primary mediators of wound debridement, osteopontin could be important in the regulation of macrophage function (Liaw *et al.*, 1995). Collagen fibril formation in the deeper dermal layers of the wounded osteopontin-null mice also appear to be affected. Osteopontin-null mice have smaller collagen fibrils than wild-type controls. Similar

to thrombospondin-2, osteopontin might affect collagen fibrillogenesis, especially at wound sites, for no differences are seen in the size of collagen fibrils in unwounded skin (Liaw *et al.*, 1995).

An additional function of osteopontin as a negative regulator of calcification is supported by a number of different studies (Giachelli *et al.*, 2005). Osteopontin inhibits apatite crystal formation *in vitro* and facilitates resorption of cellular minerals. As shown in an *in vivo* model of ectopic calcification, the capacity of osteopontin to abrogate calcification is dependent on phosphorylation of osteopontin and the presence of the integrin-binding RGD sequence in osteopontin (Giachelli *et al.*, 2005).

Osteopontin and its repertoire of cell surface receptors represent components of a pathway used by cells in need of rapid movement or migration. In addition, the ligation of osteopontin by certain cell surface receptors supports cell survival and thus provides a mechanism for a given tissue to protect a subset of cells, expressing the appropriate receptor, from apoptosis. Hence, osteopontin is a useful protein in events that require cell movement and cell survival, such as wound healing and angiogenesis, and has the potential to contribute to cancer progression (Rangaswami *et al.*, 2006).

## VI. SPARC

SPARC (secreted protein acidic and rich in cysteine; BM-40; osteonectin) was first identified as a primary component of bone but has since been shown to have a wider distribution (Brekken and Sage, 2001). Increased expression of SPARC is observed in many tissues undergoing different types of remodeling. For example, SPARC is found in the gut epithelium, which normally exhibits rapid turnover, and in healing wounds. An increase in SPARC is observed during glomerulonephritis and liver fibrosis and in association with many different tumors. Like the other matricellular proteins, SPARC interacts with the extracellular matrix by binding to collagens I, III, IV, and V (Brekken and Sage, 2001).

SPARC has also been shown to bind to a variety of growth factors present in the extracellular space. For example, SPARC binds to PDGF-AB and -BB and prevents their interaction with PDGF cell surface receptors. PDGF-stimulated mitogenesis is inhibited by the addition of SPARC (Brekken and Sage, 2001). SPARC can also prevent VEGF-induced endothelial cell growth, for it binds directly to the growth factor and thereby prevents VEGF receptor stimulation of the mitogen-activated protein kinases Erk-1 and Erk-2 (Kupprion *et al.*, 1998). *In vivo*, regulation of VEGF activity by SPARC via VEGF receptor 1 occurs during chorioidal neovascularization after injury (Nozaki *et al.*, 2006).

Interestingly, a variety of mitogenic stimulators are inhibited by SPARC in culture, some of which do not necessarily associate physically with this protein. For example, SPARC is thought not to bind to bFGF, but SPARC inhibits bFGF-stimulated endothelial cell cycle progression (Brekken

and Sage, 2001). Apparently, the effect of SPARC on cell proliferation is complex and could occur through (1) a direct prevention of receptor activation and/or (2) a pathway mediated by a cell surface receptor recognizing SPARC. To date, cell surface receptors for SPARC include stabilin-1 on macrophages and VCAM-1 on leukocytes (Kzhyshkowska *et al.*, 2006; Kelly *et al.*, 2007). Whether there are other cell surface receptors for SPARC on different cell types remains to be determined.

Another significant effect of SPARC on cells in culture is its capacity to elicit changes in cell shape. Many cell types plated on various substrata retract their filopodia and lamellipodia and assume a rounded phenotype after exposure to SPARC. Bovine aortic endothelial cells, for example, are prevented from spreading in the presence of SPARC (Brekken and Sage, 2001). Clearly, cell rounding could contribute to the inhibition of cell cycle mentioned previously; however, these two effects of SPARC appear to be independent. Motamed and Sage (1998) have shown that inhibition of tyrosine kinases reverses the counteradhesive function of SPARC but has no effect on cell-cycle inhibition. Thus, at least in endothelial cells, SPARC appears to mediate two aspects of cell behavior through different mechanisms.

Recently the targeted inactivation of the SPARC gene in mice has allowed a more thorough examination of SPARC activity. In support of SPARC as a regulator of cell proliferation, primary mesenchymal cells isolated from SPARC-null mice proliferate faster than their wild-type counterparts (Bradshaw *et al.*, 1999). The majority of SPARC-null phenotypic abnormalities, however, are seen as aberrant extracellular matrix assembly. Early-onset cataractogenesis reported in two independently-generated SPARC-null mice appears to be caused by inappropriate basement membrane synthesis by lens epithelial cells (Brekken and Sage, 2001). In the absence of SPARC, collagen IV, a SPARC ligand, is not localized to the outer border of the lens capsule, in contrast to its distribution in wild-type capsules (Yan *et al.*, 2003). In skin, collagen fibrils are small and uniform in diameter in comparison to those of wild-type dermis (Bradshaw *et al.*, 2003). In fact, fibrosis in SPARC-null mice in response to a variety of stimuli is decreased in several tissues, including lung, kidney, and skin. Hence a growing body of evidence supports a function of SPARC in assembly and stability of fibrillar collagen and basement membranes.

SPARC interaction with collagen I was recently investigated by atomic force microscopy (Wang *et al.*, 2005). SPARC bound to collagen I is predicted to interfere with integrin engagement of collagen I. Similar to inhibition of fibronectin binding by tenascin-C and consistent with a counteradhesive activity, production of SPARC might be induced by cells to modulate interaction of integrin receptors with collagens.

In addition to its effect on cell cycle, recent evidence shows that SPARC influences TGF- $\beta$ -dependent pathways in some cell types. Mesangial cells isolated from SPARC-null mice show a decrease in collagen I expression, accompa-

nied by a decrease in the levels of the cytokine TGF $\beta$ -1, in comparison to wild-type cells (Francki *et al.*, 1999). TGF- $\beta$  is a known positive regulator of extracellular matrix synthesis. Addition of recombinant SPARC to SPARC-null mesangial cultures restores the levels of collagen I and TGF- $\beta$  nearly to those of wild-type cells (Francki *et al.*, 1999). SPARC also promotes the TGF- $\beta$  signal transduction pathway in epithelial cells (Schiemann *et al.*, 2003). Thus it appears that SPARC can act as a regulator of TGF- $\beta$  activity and, perhaps by extension, influences collagen I production.

Once again, we see SPARC as an example of a multifunctional protein able to regulate cell shape and modulate growth factor activity. In addition, SPARC appears to be a key factor in extracellular matrix assembly in both basal lamina and interstitium. Consistent with these functions, a homolog of SPARC termed *hevin* was recently shown to be counteradhesive and modulatory of extracellular matrix structure (Sullivan and Sage, 2004).

## VII. CONCLUSIONS

In addition to the proteins described here, others are potential candidates for inclusion in the family of matricellular proteins. These include small proteoglycans, such as the matrix-associated protein decorin, which has been shown to be an endogenous regulator of TGF- $\beta$  activity (Border *et al.*, 1992), as well as certain members of the recently classified CCN gene family (Brigstock *et al.*, 2003). The CCN proteins are secreted and modular and exhibit functions based, at least in part, on integrin-mediated mechanisms. Whereas CCN1 (CYR 61) enhances apoptosis in fibroblasts, endothelial cell adhesion to CCN1 promotes cell survival (Todorovic *et al.*, 2005). Further analysis of these proteins and their actions will expand our comprehension of matricellular proteins and the functions they serve in regulating cell interaction with components of their immediate environment.

In any cellular environment, numerous extracellular signals are in place to control cell behavior. In adult tissues, injury and disease both lead to a wide-scale release of multiple factors, either secreted from cells or sequestered in the extracellular matrix, that are capable of eliciting potent cellular responses. Appropriately, an increase in the expression of many matricellular proteins is associated with pathological events. Hence, the matricellular proteins appear to be ideally suited to act as modulators of these extracellular signals. They are able to serve as bridges between the extracellular matrix and cell surface receptors, such that cell shape changes or cell movements can be initiated prior to matrix breakdown or synthesis. At least three matricellular proteins, thrombospondin-2, osteopontin, and SPARC, appear to participate in matrix synthesis, through either the promotion of collagen fibrillogenesis or the enhancement of collagen production. Matricellular proteins can either inhibit or potentiate specific growth factor signal transduction pathways. Thus, different growth factor effects may be

amplified or subdued by the presence or absence of these proteins. The fact that multiple receptors exist for most of the matricellular proteins allows for diverse functional consequences for different cell types in a complex tissue in response to a matricellular ligand. A given repertoire of cell

surface receptors can stimulate (or inhibit) a particular pathway in a cell-type-dependent manner. Apparently, evolution has fine-tuned these proteins to serve as specialized mediators of extracellular signals that provide a coordinated, efficient resolution of tissue injury.

### I. INTRODUCTION

Tissue remodeling is an essential component in the process of wound healing and thus in the normal maintenance and survival of all organisms. Tissue remodeling occurs throughout the entire temporal span of injury and repair. However, although abundant evidence using histologic methods has accumulated to detail the sequence of appearance of cell types that characterize wound healing, the mechanisms that initiate and sustain the process remain to be established (Ross, 1968; Deuel *et al.*, 1991; Pierce and Mustoe, 1995). What has become increasingly clear from analysis of properties of growth factors and other cytokines is their importance in the initiation and propagation of the processes that begin with injury and end with a healed wound. These factors and their receptors dictate cell type and tissue specificity of response, and the regulation of their genes at the level of transcription has established the time course of their expression. Their properties are those needed in the wound-healing process.

Because growth factors applied directly to wounds accelerate the normal process of wound healing *in vivo*, it seems likely that the properties described for the growth factors *in vitro* are recapitulated *in vivo* (Grotendorst *et al.*, 1985; Paulsson *et al.*, 1987; Sprugel *et al.*, 1987; Pierce *et al.*, 1988, 1989, 1992; Terracio *et al.*, 1988; Greenhalgh *et al.*, 1990; Hart *et al.*, 1990; Quaglini *et al.*, 1990; Shaw *et al.*, 1990; Antoniades *et al.*, 1991; Deuel *et al.*, 1991; Mustoe *et al.*, 1991; Nagaoka *et al.*, 1991; Pepper *et al.*, 1991; Soma *et al.*, 1992; Reuterdaahl *et al.*, 1993; Sundberg *et al.*, 1993; Pierce and Mustoe, 1995). It is also important to recognize that properties of growth factors may be important in the development of abnormalities in the vascular wall, such as atherosclerosis, and in tumor growth, suggesting that deregulation of growth factors and other cytokines may have serious consequences for the host and that tight regulation of their activities is needed for normal function (Broadley, 1989; Golden, 1991; D'Amore, 1993; Forsberg, 1993). Compelling evidence is therefore available to indicate

the importance of growth factors and other cytokines in the wound-healing process. However, the specific roles of these endogenous factors remain to be established in normal wound healing, and the signals that regulate the sites and time of their expression are little understood.

This chapter provides an overview of roles of the platelet-derived growth factor (PDGF) and other cytokines as models of factors that initiate and propagate a number of the normal processes required for the orderly progression of inflammation, tissue remodeling, and repair.

PDGF was initially described as a potent mitogen. However, PDGF directs cell migration, activates diverse cell types, and up-regulates expression of genes that otherwise are quiescent and not expressed at significant levels. This last property of PDGF appears to establish gene activation pathways that are unique to different cell types. It provides a temporal sequence of expression of different pathways that may be of central importance in tissue remodeling and repair, a property required of a signaling molecule in the wound-healing process. Experiments in which PDGF has been directly applied to wounds have shown that PDGF accelerates the normal healing process; it does not distort it, indicating that PDGF can up-regulate genes needed for wound healing in a precise order. However, there is little if any information to establish the relative contributions of PDGF and different growth factors to the healing of normal wounds, and thus experimental strategies continue to focus on *in vitro* properties of growth factors. Additional models and reagents are needed to test these results directly *in vivo*.

## II. WOUND HEALING

Normal wound healing may be separated operationally into different stages that overlap and proceed in a clear sequence to a healed wound. Initially, platelets release granule products, and products of the coagulation process are deposited locally. The sequential migration of neutrophils, monocytes, and fibroblasts into wounds begins immediately and continues over the first several days. Wound macrophages (derived from circulating monocytes) and fibroblasts become activated, to initiate a cascade of new gene expression that results in *de novo* synthesis of growth factors and other cytokines, synthesis of extracellular matrix proteins (including collagen), and proliferation of fibroblasts. Later, tissue remodeling results in active collagen turnover and cross-linking that lasts from two weeks to one year postwounding.

Factors that arise locally account for the cell migration and activation of fibroblasts in wounds (Arey, 1936; Dunphy, 1963; Liebovich, 1975). However, circulating platelets are invariably associated with wounds and are now known to release factors originally stored within intracellular compartments, such as the platelet granules, into wounds. These factors attract neutrophils, monocytes, fibroblasts, and other (tissue-specific) cells, such as the smooth muscle

cells. Platelets are now considered to be important mediators in the initiation of inflammation and subsequent tissue remodeling and repair. Platelet release is initiated by products of coagulation, such as thrombin, and by platelet exposure to foreign surfaces, such as collagen. Platelet release occurs within seconds of platelet activation. Synthesis of other potent molecules, such as the prostaglandins and leukotrienes, also influences intracellular responses and extracellular activities that contribute significantly to early events within wounds. These factors also initiate the transcriptional activation of genes that encode proteins with other signaling roles, serving to attract inflammatory cells locally. Because inflammatory cells are in close proximity to platelets in a number of models of inflammation (immune complex disease and atherosclerosis), it is likely that platelets are important in the earliest stages of different inflammatory states. Platelets and inflammatory cells appear to “talk” to each other in essential ways, through the release of cytokines and growth factors to attract additional inflammatory cells and to activate transcription of factors that regulate or encode additional mediators of inflammation and wound repair. Studies with PDGF in the *in vivo* context support these functional roles for platelet secretory proteins.

PDGF was originally identified as a potent mitogen in serum for mesenchymally derived cells. Purified human PDGF is predominantly a heterodimeric molecule consisting of two separate but highly related polypeptide chains (A and B chains) (Hart *et al.*, 1990). The B chain of PDGF is ~92% identical with the protein product of the *v-sis* gene, the oncogene of simian sarcoma virus, an acute transforming retrovirus, and thus is a protooncogene. Both BB and AA homodimers of PDGF also have been isolated from natural sources and have been shown to be expressed in many cell types of diverse origins, including macrophages, endothelial cells, smooth and skeletal muscle cells, fibroblasts, glial cells, and neurons. These cells secrete molecules with PDGF-like activity. The detection of these molecules has been associated with the expression of the mRNAs for A and B chains that can be specifically associated with chain isoforms of PDGF. However, identification of the specific isoform(s) at the level of the protein has been difficult because reagents to detect each isoform specifically are not readily available. Multiple PDGF-AA transcripts have been detected in cells that appear to be alternative splice variants of a single seven-exon gene (Collins *et al.*, 1987; Tong *et al.*, 1987). Three splice variants result in short and long processed proteins, 110 and 125 amino acids (Collins *et al.*, 1987; Tong, Auer *et al.*, 1987; Matoskova *et al.*, 1989) in length, and may be important because of differential regulation of the transcripts and because they appear to bind with different affinities to the extracellular matrix (Ostman *et al.*, 1989; Nagaoka *et al.*, 1991). The transcripts for both proteins are widely expressed in multiple cell types.

Each of the three isoforms (BB, AB, and AA) binds to the PDGF- $\alpha$  receptor, whereas only the BB isoform binds with

significant affinity to the type of PDGF receptor- $\beta$  (Hart *et al.*, 1988; Heldin *et al.*, 1988; Matsui *et al.*, 1989). Both receptor types are highly homologous transmembrane tyrosine kinases and are expressed in a cell type-specific manner, not only governing cell target specificity of the PDGF response (Eriksson *et al.*, 1992), but also adding both complexity and thus diversity to the potential roles of PDGF in inflammation and wound healing. The functions of PDGF *in vivo* thus are regulated by the need for specific ligand-receptor interactions to transduce the signals required for various functions of PDGF and the up-regulation of other genes that propagate the cascade of events initiated by PDGF.

### III. GROWTH FACTORS AND CYTOKINES ACTIVE AS EARLY MEDIATORS OF THE INFLAMMATORY PROCESS

In order to investigate and thus to understand the roles of growth factors and other cytokine mediators of inflammation, tissue remodeling, and wound healing, experimental strategies were designed first to isolate and characterize these factors, to analyze their properties *in vitro*, to determine the sites and levels of expression achievable *in vivo*, and to develop reagents and experimental models to analyze normal functions of growth factors and other cytokines in the intact animal. Early work focused on the roles of PDGF as a mitogen, largely because it was the first mitogen to be purified. However, in addition to the striking potency of PDGF as a mitogen, PDGF is strongly chemotactic for human monocytes and neutrophils, a property of PDGF that may be more important in early phases of inflammation. Optimal concentrations of PDGF that are required for maximum chemotactic and mitogenic activity are 20 and 1 ng/mL, respectively (Deuel *et al.*, 1982), concentrations of PDGF that are well below those measured in human serum (~50 ng/mL) (Deuel *et al.*, 1982). Because platelets aggregate and release at wound sites, the concentrations of PDGF at these sites may be substantially higher than those in serum. Furthermore, PDGF is a chemoattractant for fibroblasts and smooth muscle cells but requires a somewhat higher concentration (Seppa *et al.*, 1981; Senior *et al.*, 1983), suggesting that PDGF may also be involved later in wound healing through its influence on fibroblast and smooth muscle cell movement (Senior *et al.*, 1983).

In contrast to the PDGF AB isoform, the chemotactic potential of PDGF AA has been controversial. This controversy was important to resolve because the A chain homodimers of PDGF (PDGF AA) are widely expressed in normal and transformed cells. However, PDGF AA has been independently established as a strong chemoattractant for human monocytes, granulocytes, and fetal bovine ligament fibroblasts. Relevant to the roles of monocytes/tissue macrophages in the wound-healing process, it was shown that highly purified (>98%) monocytes require the addition of

lymphocytes or interleukin 1 (IL-1) for chemotactic responsiveness to PDGF AA but not for the chemotactic activity of formyl-methionyl-leucyl-phenylalanine (fMLP) or C5a. Monocytes therefore require activation before becoming responsive to PDGF as a chemoattractant. Activation of lymphocytes or exogenous cytokines is required for monocytes to respond hemotactically to PDGFAA but not to fMLP or C5a, suggesting that regulation of the chemotactic response of the monocyte to PDGF AA by the lymphocyte or cytokines may be another regulatory level of importance in the ultimate pathway to tissue remodeling and wound healing *in vivo* (Shure *et al.*, 1992).

The effect of PDGF on cell migration was extended to other platelet granule proteins when it was shown that  $\beta$ -thromboglobulin (TG- $\beta$ ) is a highly active chemotactic factor for fibroblasts (Senior *et al.*, 1983). Platelet factor 4 also is a potent chemoattractant. Lymphokines, a peptide derived from the fifth component of complement, collagen-derived peptides, fibronectin, tropoelastin, and elastin-derived peptides are wound-associated factors that also are potent chemoattractants with differing cell type specificity (Postlethwaite *et al.*, 1976, 1978, 1979; Senior *et al.*, 1982).

In addition to its roles in cell migration, PDGF activates the polymorphonuclear leukocyte (Tzeng *et al.*, 1984) and is capable of inducing monocyte activation responses, as evaluated by generation of superoxide anion ( $O_2^-$ ) from the membrane-associated oxidase system, release of granule enzymes, and enhanced cell adherence and cell aggregation. Superoxide anion release in monocytes is observed at 10 ng/mL, and the levels of PDGF-dependent release are comparable to the release induced by  $10^{-7}$  mL/L fMLP. The potency of PDGF to induce this response in monocytes is of the same magnitude as that observed in polymorphonuclear leukocytes (PMNs). Similarly, lysozyme release and monocyte adherence are increased in a dose-dependent manner in response to PDGF and achieve maximal responses at 40 ng/mL PDGF. The PDGF concentration required to achieve maximal monocyte aggregation was twofold (60 ng/mL) that found for PMNs, and, at this concentration of PDGF, it is likely to occur only in the immediate vicinity of platelet aggregates. PDGF thus induces the full sequence of cell activation events in human monocytes, similar to human PMNs, and this property may well be of major significance in the release of enzymes and other factors required to begin the process of tissue breakdown required for remodeling.

Other early cellular effects important to inflammation and repair also may be initiated by the release of PDGF from platelets and cells within the wound. For example, collagenase expression was studied in normal human skin fibroblasts that were cultured for 24 h in the presence of PDGF. Collagenase release is required for the breakdown of collagen necessary for the later remodeling of collagen and for tissue repair (Bauer *et al.*, 1985; Pierce *et al.*, 1989). A

dose-dependent, saturable increase in collagenase activity in culture media was observed with paralleled increases in immunoreactive collagenase protein, suggesting the enhanced synthesis of an immunologically unaltered enzyme. The specificity of this effect was demonstrated by collagenase stimulatory effect with that on total protein synthesis and DNA synthesis. Under *in vitro* conditions that produced a 2.5-fold increase in collagenase synthesis, there was an ~20% increase in total protein synthesis and no detectable change in DNA synthesis. In addition, as a second control, platelet factor 4, another platelet-derived protein, caused a <20% increase in collagenase expression. In time-course studies, stimulation of collagenase synthesis was first observed 8–10 h after exposure to the growth factor. Furthermore, when cells were exposed to PDGF for ~24 h, an increase in the rate of collagenase synthesis was seen for ~6 h after PDGF was removed, after which the rate reverted to control levels. Growth factor-regulated expression of collagenase may be of unique importance to tissue remodeling, because it occurs somewhat later than the most immediate responses to PDGF at the time collagen degradation may be essential for progression of remodeling and tissue repair (Bauer *et al.*, 1985).

Patients with Werner's syndrome, an autosomal recessive disorder, undergo an accelerated aging process and premature death. Fibroblasts from such patients typically grow poorly in culture but have a markedly attenuated mitogenic response to platelet-derived growth factor and fibroblast growth factor (FGF). In contrast, these cells have a full mitogenic response to fetal bovine serum. The Werner's syndrome cells express high constitutive levels of collagenase *in vitro*. However, no induction of collagenase occurs in the Werner's syndrome fibroblasts in response to PDGF. The coupling of the failure of one or more PDGF-mediated pathways in Werner's syndrome cells with the phenotype of this disorder is perhaps important support for roles of PDGF and other cytokines in tissue remodeling (Bauer *et al.*, 1986).

#### IV. INFLAMMATORY RESPONSE MEDIATORS ACTIVATE TRANSCRIPTION OF QUIESCENT GENES

Another potentially highly important role of PDGF and other growth factors and cytokines in wound healing is the up-regulation of early-intermediate response genes in cells activated by PDGF. In response to PDGF and other cytokines, fibroblasts and other cells initiate transcription and expression of genes that are dormant in the absence of stimulation. The products of some of these genes are important in the intracellular propagation of the mitogenic signal, but others are important for intercellular communication, direct cell migration, and activation of cells of different types. The products of these genes (Cochran *et al.*, 1983; Kohase *et al.*, 1987; Rollins *et al.*, 1988; Pierce *et al.*, 1989a, 1989b) may

serve to coordinate a second wave of diverse responses designated to combat wound infection and to initiate and propagate the healing process.

The PDGF early/early-intermediate response genes *JE* and *KC* were first isolated by differential colony hybridization (Cochran *et al.*, 1983) and only later were identified as cytokines belonging to a newly described superfamily of small inducible genes (SIGs) (Kawahara and Deuel, 1989) (now known as the chemokine family). This family surprisingly includes platelet granule proteins, such as the platelet basic protein and platelet factor 4. These PDGF-induced cytokines suggest pathways of gene activation that may account in part for cell type specificity and the normal temporal responses of wound healing. The *JE* gene encodes a basic (PI = 10.4) 148-amino acid polypeptide (Rollins *et al.*, 1988; Kawahara and Deuel, 1989) that shows 82% amino acid identity with the murine *JE* gene (Timmers *et al.*, 1990). Both rat and murine *JE* gene products contain N-terminal hydrophobic leader sequences, virtually identical alternating hydrophobic and hydrophilic domains, a single N-linked glycosylation site at position 126 that is conserved in both the murine and rat *JE* genes, and identical intron–exon splice junctions.

The importance of the *JE* gene product was suggested when the human homolog of the rodent *JE* gene was identified as monocyte chemotactic protein-1 (MCP-1) (Yoshimura *et al.*, 1989b). MCP-1 is identical with monocyte chemotactic and activating factor (MCAF) (Furutani *et al.*, 1989), MCP (Decock *et al.*, 1990), HC11 (H. C. Chang *et al.*, 1989), and the smooth muscle cell chemotactic factor (SMC-CF) (Graves *et al.*, 1989). Both the MCP-1 and rodent *JE* genes are induced in fibroblasts by PDGF [also serum, phorbol myristate acetate (PMA), double-stranded RNA, and interleukin-1], and each cross-hybridizes to the same bands on Southern blots (Rollins *et al.*, 1989). Antibodies raised to the murine *JE* cross-react with MCP-1. MCP-1 is a potent factor chemotactic for monocytes but not for neutrophils (Yoshimura *et al.*, 1989), a specificity of cell type recognition that is not seen with many of the other chemotactic factors that have been characterized (Senior *et al.*, 1989), suggesting a unique role in the inflammatory process. Other cytokines with sharply defined functional activity have also been identified in the chemokine family. MCP-1/SMC-CF or related molecules appear to be the major chemotactic factor(s) released by a number of tumor cell lines as well (Graves *et al.*, 1989). This relationship calls to attention the surprising parallels that have been found between tumor cells and activated cells such as the fibroblast.

The genes of this family are normally not expressed at detectable levels but can be induced in the presence of the appropriate stimuli. Remarkably, each of the inducers has an important role in cell growth, inflammation, or immune responses. Increasing knowledge of this family of genes and their products has suggested an enlarging role for PDGF and other cytokines in the sequential and cell type-specific

development of inflammation and the evolution of the wound-healing process (Kawahara *et al.*, 1991).

## V. BIOLOGIC PROPERTIES OF SIG (CHEMOKINE) FAMILY MEMBERS

Neutrophil activation protein/IL-8 (NAP-1/IL-8) is a highly cell type-specific activator and chemotactic factor for neutrophils but not for monocytes (Yoshimura *et al.*, 1987). NAP-1/IL-8 was identified in conditioned medium of lipopolysaccharide-stimulated monocytes (Walz *et al.*, 1987; Yoshimura *et al.*, 1987), and its gene (3-10C) was cloned independently as a staphylococcal enterotoxin A-induced gene from peripheral blood leukocytes (Schmid and Weissmann, 1987). NAP-1 is also chemotactic for T-lymphocytes and basophils (Larsen *et al.*, 1989; Leonard *et al.*, 1990) and is the N-terminal processed form of endothelial-derived leukocyte adhesion inhibitor (LAI), an inhibitor of neutrophil adhesion that protects endothelial cells from neutrophil-mediated damage (Gimbrone *et al.*, 1989; Kawahara *et al.*, 1991).

MCP-1 is chemotactic for monocytes. It was purified from the culture media of human glioma cell line U-105MG (Yoshimura *et al.*, 1989), THP-1 cells (Matsushima *et al.*, 1989), phytohemagglutinin-stimulated mononuclear cells (Robinson *et al.*, 1989), and double-stranded RNA [poly(rI). poly(rC)]-stimulated fibroblasts (Van Damme *et al.*, 1989; Kawahara *et al.*, 1991).

Macrophage inflammatory protein-1 (MIP-1) was purified in two forms (MIP-1, MIP-2) from lipopolysaccharide-stimulated RAW264.7 cells and is chemotactic for polymorphonuclear cells (Wolpe *et al.*, 1988). MIP-1 induces oxidative burst and degranulation in neutrophils and promotes inflammatory reactions. MIP-1 is also a prostaglandin-independent pyrogen (Davatelis *et al.*, 1989). MIP-2 is a potent chemotactic factor for neutrophils and causes neutrophil degranulation, but it does not induce an oxidative burst (Kawahara *et al.*, 1991).

Platelet factor 4 (PF4) is a platelet granule protein that is chemotactic for both neutrophils and monocytes (Deuel *et al.*, 1981). It has immunoregulatory activity (Katz *et al.*, 1986) and can inhibit angiogenesis (Maione *et al.*, 1990). Platelet basic protein, connective tissue-activating peptide III (CTAP-III),  $\beta$ -thromboglobulin, and neutrophil-activating peptide-2 (NAP-2) are N-terminal proteolytic processed forms of a single gene product, CTAP-III is mitogenic for human dermal fibroblasts (Castor *et al.*, 1983), and NAP-2 is induced in monocytes when they are exposed to lipopolysaccharides and can stimulate the release of elastase from human neutrophils (Walz *et al.*, 1987; Kawahara *et al.*, 1991).

Melanoma growth stimulatory activity (MGSA) is a mitogen for cultured melanoma and pigmented (nevus) cells (Richmond *et al.*, 1988). Primary melanoma cells secrete MGSA, and for this reason it has been suggested

to be an autocrine regulator of growth. The protein product of MGSA is identical to the *gro- $\alpha$*  gene isolated by subtractive hybridization of mRNA from transformed hamster CHEF/16 cells. The rat analog, cytokine-induced neutrophil chemoattractant (CINC) is chemotactic for neutrophils (Watanabe *et al.*, 1989). The murine analog (KC) is a PDGF-inducible gene (Cochran *et al.*, 1983; Kawahara *et al.*, 1991).

## VI. REGULATION OF JE GENE EXPRESSION BY GLUCOCORTICOIDS

The role of PDGF and other cytokines in the induction of otherwise unexpressed genes has resulted in additional insights into the wound-healing process. The addition of dexamethasone and other steroid drugs to PDGF- and serum-stimulated BALB/c 3T3 fibroblasts prevents the PDGF and serum-dependent induction of the *JE* gene in a dose-dependent manner. Furthermore, induction follows the rank order of potency expected for glucocorticoid receptor-mediated antiinflammatory activity. The inhibition appears to be highly specific for inflammatory mediators, suggesting that the role of PDGF in the induction of selective SIG family members may be a highly important step at which glucocorticoids negatively influence both inflammation and repair (Kawahara *et al.*, 1991).

## VII. GROWTH FACTORS AND ACCELERATED HEALING

Much new information about the roles of growth factors and other cytokines has resulted from the direct application of PDGF to experimental wounds in animals. Morphometric methods and histologic techniques have been used to compare wounds treated with supraphysiological concentrations of growth factors to untreated wounds. This approach, coupled with the *in vitro* approaches cited earlier, has greatly clarified roles of PDGF-enhanced tissue repair and remodeling and has stimulated similar experiments with other cytokines as well.

In one set of experiments, exogenous PDGF was applied locally, and once only, to incisional wounds in rats and rabbits. PDGF accelerated tissue repair in a dose-dependent manner (Pierce *et al.*, 1988, 1991). The single application of PDGF to rat incisions enhanced by 150–170% over a three-week time course the strength required to “break” the healing wound (Pierce *et al.*, 1988). PDGF accelerated healing by four to six days over the first two weeks and by five to ten days between two and seven weeks postwounding (Pierce *et al.*, 1989). At 89 days postwounding, both PDGF-treated and control wounds had achieved similar wound strength (–90% of unwounded dermis), and doses therefore induced a long-lasting enhancement rate of healing, supporting the view that PDGF and other growth factors initiate events required for normal healing of

wounds and enhance the normal rate of wound healing and tissue remodeling.

In these wounds, PDGF significantly increased the rate of increase of cellularity and granulation tissue formation. The early appearance of wounds treated with PDGF is that of a highly exaggerated inflammatory response. An increased neutrophil influx was seen at 12 h. A marked increase in influx of macrophages and, later, fibroblasts was found from day 2, persisting through 21 days postwounding (Pierce *et al.*, 1988). Furthermore, enhanced cellular function of fibroblasts could be established in treated wounds. Increased numbers of procollagen-containing fibroblasts were strikingly apparent as early as two days postwounding. At 28 days, it was not possible to distinguish activated from nonactivated fibroblasts in treated and untreated wounds. These results indicate that PDGF accelerates the healing response.

Furthermore, within the limits of detection, PDGF also results in a healed wound that cannot be distinguished from its untreated counterpart (Pierce *et al.*, 1989). PDGF also appears to be multifunctional in diverse ways, perhaps through the recruitment and activation of macrophages and fibroblasts and through up-regulation of expression at different cytokine genes whose functions and cell type specificity provide additional diversity to the normal healing process.

Another polypeptide growth factor that is stored in the granules of platelets, transforming growth factor  $\beta$  (TGF- $\beta$ ), may also be very important in tissue repair (Sporn *et al.*, 1986). Both PDGF and TGF- $\beta$  increase collagen formation, DNA content, and protein levels in wound chambers implanted in rats (Sporn *et al.*, 1983; Grotendorst *et al.*, 1985). TGF- $\beta$  enhances the reversible formation of granulation tissue when injected subcutaneously into newborn mice (Roberts *et al.*, 1986). A single application of human TGF- $\beta$  at the time of wounding advanced by two to three days the breaking strength required to rupture the incision margins when assayed at one week. The marked augmentation of wound healing using both human PDGF (hPDGF) and recombinant *c-sis* homodimers (rPDGF-B) revealed a unique pattern of response when compared with the results obtained with TGF- $\beta$  (Mustoe *et al.*, 1987; Pierce *et al.*, 1988).

Circular excisional wounds also were placed through the dermis of the rabbit ear to the level of underlying cartilage, a model that does not allow contraction from the wound margins (Mustoe *et al.*, 1991). Ingrowth of extracellular matrix and granulation tissue was measured by histomorphometric techniques (Mustoe *et al.*, 1991). A single application of PDGF increased granulation tissue ~200% at seven days in association with a predominance of fibroblasts and collagen-containing extracellular matrix (Mustoe *et al.*, 1991). The healed wound again was indistinguishable from the control, non-PDGF-treated healed wound. Interestingly, PDGF also nearly doubled the rate at which re-

epithelialization occurred, and neovascularization was prominent in granulation tissue. These unexpected findings, in view of the known cell type specificity of PDGF, suggested up-regulation either of PDGF receptors or of other cytokine genes, with resultant cell type-specific epithelial and/or endothelial cell functions. Whereas again the mechanisms of the PDGF effect are not established, the influence of a single application of a growth factor remarkably accelerated the inflammatory response and the subsequent tissue remodeling to result in a healed wound of normal appearance.

In this model, PDGF accelerated deposition of matrix largely composed of glycosaminoglycans and later of collagen (Pierce *et al.*, 1991). The normal sequence in repair and the acceleration of wound healing, to all appearances, are identical to those in an untreated wound, supporting the view that the role of PDGF is to accelerate normal wound healing in human wounds. It has been demonstrated in human wounds that PDGF AA expression is increased within healing pressure ulcers. The accumulation of PDGF AA is accompanied by activated fibroblasts, extracellular matrix deposition, and active neovessel formation. However, far less PDGF AA is present in chronic nonhealing wounds. Thus, up-regulation of PDGF AA may be important in the normal repair process as well (Robson *et al.*, 1992; Mustoe *et al.*, 1994; Pierce *et al.*, 1994).

PDGF BB, bFGF, and epidermal growth factor (EGF), applied locally at the time of wounding, cause a twofold increase in complete reepithelialization of treated wounds, whereas TGF- $\beta$  significantly inhibits reepithelialization. Both PDGF BB and TGF- $\beta$  increased the depth and area of new granulation tissue, the influx of fibroblasts, and the deposition of new matrix into wounds. Explants from treated wounds remained metabolically more active than controls, incorporating 473% more [ $^3$ H]-thymidine into DNA and significantly more [ $^3$ H]-leucine and [ $^3$ H]-proline into collagenase-sensitive protein (Mustoe *et al.*, 1991). The different response to growth factors underscores the importance of tissue and cell type specificity of the growth factors to tissue repair and perhaps also the need for exquisite timing of induction of different factors in the orderly progression of the healing process.

The use of these wound-healing models provided the basis to suggest at least one mechanism whereby PDGF may function *in vivo* (Mustoe *et al.*, 1989; Pierce *et al.*, 1989). Animals that were pretreated with glucocorticoids or total-body irradiation to reduce circulating monocytes to non-detectable levels had a sharply reduced influx of wound macrophages. PDGF was tested in these animals. It was shown that the PDGF-induced acceleration of incisional repair was abrogated in glucocorticoid-treated animals (Pierce *et al.*, 1989). However, PDGF attracted a significant influx of fibroblasts into the compromised wounds of animals. The fibroblasts lacked procollagen type I, suggesting the requirement of the wound macrophage to support

stimulation of fibroblast procollagen type I synthesis. PDGF alone does not stimulate procollagen type I synthesis when added directly to fibroblasts *in vitro* (Blatti *et al.*, 1988; Rossi *et al.*, 1988). However, PDGF-activated macrophages synthesize TGF- $\beta$  (Pierce *et al.*, 1989), a potent activator of the fibroblast procollagen type I gene (Ignatz and Massague, 1986; Rossi *et al.*, 1988). It is suggested that TGF- $\beta$  may be a second signal messenger to induce collagen formation in PDGF-treated wounds. This suggestion is supported directly in experiments in which macrophages and fibroblasts in PDGF-treated incisional wounds were shown to contain increased levels of intracellular TGF- $\beta$  (Pierce *et al.*, 1989).

The results with wound-healing models and PDGF have illustrated much about inflammation, tissue remodeling, and the process of wound healing. Other *in vivo* models of PDGF-treated wounds also indicate that PDGF stimulates normal and reverses deficient dermal repair (Grotendorst *et al.*, 1985; Lynch *et al.*, 1987; Sprugel *et al.*, 1987; Greenhalgh *et al.*, 1990) and have suggested roles for this growth factor in inflammation (Circolo *et al.*, 1990), uterine smooth muscle hypertrophy (Mendoza *et al.*, 1990), lens growth and transparency (Brewitt and Clark, 1988), and central nervous system gliogenesis (Richardson *et al.*, 1988). What may be the most important conclusions are that PDGF has the potential to initiate and accelerate the process and to sustain the process to an endpoint that is effectively identical to untreated wounds. The most important mechanisms of its activity may be the consequences of its potent chemotactic activity and its ability to induce multiple autocrine loops that lead to an endogenous cascade of new gene activation and cell-specific cytokine synthesis within the healing wound. Clinical trials have now established the efficacy of PDGF in advancing the healing of diabetic ulcers. PDGF is now "in the clinic."

## VIII. ROLE OF BASIC FIBROBLAST GROWTH FACTOR AND ANGIOGENESIS

Normal wound healing can be divided into three phases: inflammation, fibroplasia, and maturation provoked by liberated angiogenic factors. Vessel-dense granulation tissue is central to the process of tissue repair. The formation of new blood vessels provides a route for oxygen and nutrient delivery as well as a conduit for components of the inflammatory response. Endogenous bFGF, like PDGF, is also found in the wound site and is presumed to be a necessary part of natural wound healing. Mechanically damaged endothelial cells and burned wound tissue release significant amounts of bFGF into the wound area, suggesting that damaged endothelial cells at the cut edges of blood vessels, as well as other damaged cells at the site of a wound, may provide an early source of bFGF (McNeil *et al.*, 1989; Muthukrishnan *et al.*, 1991; Gibrán *et al.*, 1994). A slightly later and more sustained supply of bFGF at the wound site is delivered by the invading activated macrophages (Baird *et al.*, 1985; Rappolee

*et al.*, 1988; Fiddes *et al.*, 1991). Moreover, recombinant bFGF has been shown to enhance healing, if added exogenously to a wound site (Brew *et al.*, 1995). It is now clear that bFGF can act as an angiogenic factor *in vitro* (Montesano *et al.*, 1986) and *in vivo* (Folkman and Klagsbrun, 1987), directing endothelial cell migration and proliferation, and that bFGF is a mitogen to endothelial cells. It also up-regulates expression of plasminogen activator and the  $\alpha v \beta 3$  integrin that promotes both migration of endothelial cells and luminal formation (Pepper *et al.*, 1991; Friedlander *et al.*, 1995). The effects of stimulating endothelial cell growth, capillary differentiation, and connective tissue cell growth by bFGF contribute to wound healing and tissue regeneration (Gibrán *et al.*, 1994; Steenfos, 1994).

Wound healing involves the interactions of many cell types and is controlled in part by growth factors. Intercellular communication mediated by gap junctions is considered to play an important role in the coordination of cellular metabolism during the growth and development of tissues and organs. Basic fibroblast growth factor, known to be important in wound healing, has been found to increase gap junctional protein annexin 43 expression and intercellular communication in endothelial cells and cardiac fibroblasts (Abdullah *et al.*, 1999). It has been proposed that an increased coupling is necessary for the coordination of these cells in wound healing and angiogenesis and that one of the actions of bFGF is to modulate intercellular communication. In a variety of animal models, exogenous bFGF has been shown to accelerate wound healing by speeding granulation tissue formation and increasing fibroblast proliferation and collagen accumulation at the site of a subcutaneously implanted sponge in rats (Davidson *et al.*, 1985; Buckley-Sturrock *et al.*, 1989). Fresh wound tensile strength has also been increased (McGee *et al.*, 1988). However, the greatest benefit from the application of exogenous bFGF can probably be obtained in cases in which wound healing is impaired. Research on skin flaps indicates that bFGF has the potential to increase viability by accelerating flap revascularization when administered in a sustained-release manner (Hom and Winters, 1998). This may have applications to open or nonunion fractures with impaired wound healing. Despite encouraging experimental results to date coming from studies showing that treatment of genetically diabetic mice with recombinant bFGF not only increased fibroblast and capillary density in the wound but also accelerated wound closure, clinical application of recombinant human bFGF has fallen short of expectations. In a randomized double-blind placebo-controlled study, direct application of bFGF to nonhealing ulcers of diabetic patients did not accelerate wound healing (Richard *et al.*, 1995). In a subsequent randomized placebo-controlled trial to study the effect of recombinant bovine bFGF on burn healing, all patients treated with bFGF had faster granulation tissue formation and epidermal regeneration, compared with those in the placebo group. Superficial and deep second-degree burns

treated with bFGF healed in a mean of 9.9 days (SD 2.5) and 17.0 days (SD 4.6), respectively, compared with 12.4 (2.7) and 21.2 (4.9) days. No adverse effects were seen locally or systemically with bFGF. It is indicated that bFGF effectively decreased healing time and improved healing quality. Clinical benefits for use of bFGF in burn wounds would be shorter hospital stays and the patients' skin quickly becoming available for harvesting and grafting (Fu *et al.*, 1998).

## IX. PLEIOTROPHIN REMODELS TUMOR MICROENVIRONMENT AND STIMULATES ANGIOGENESIS

Pleiotrophin (PTN, *Ptn*) is a PDGF-inducible, heparin-binding cytokine and thus a downstream effector of PDGF. Pleiotrophin was first purified in this laboratory as an 18-kD heparin-binding, mitogenic polypeptide from bovine uterus (Milner *et al.*, 1989) and as neurite-outgrowth-promoting activity from neonatal rat brain (Rauvala, 1989); it is a lysine-rich, highly basic protein of 168 amino acids with a 32-amino acid signal peptide that is nearly 50% identical in amino acid sequence with Midkine (MK, *Mk*) (Li *et al.*, 1990), a gene expressed in early stages of retinoic acid-induced differentiation in mouse embryonal carcinoma cells (Kadomatsu *et al.*, 1988). Pleiotrophin and *Mk* are the only known members of this family. Pleiotrophin lacks homology with members of the heparin-binding growth factor (HBGF) family of structurally related polypeptides (Goldfarb, 1990).

The *Ptn* gene is expressed during neuroectodermal and mesodermal development but not in endoderm, ectoderm, or trophoblasts (Silos-Santiago *et al.*, 1996). Expression levels of *Ptn* peak in late embryonic development and the immediate postnatal period. They correlate with peaks of growth and differentiation in both neuroectoderm and mesoderm (Rauvala, 1989; Li *et al.*, 1990). In adults, PTN expression is limited to selected cell populations and is constitutive; however, the *Ptn* gene expression is up-regulated after injury and during repair. In cultured cells, its expression is modulated by growth factors, including PDGF, bFGF, and steroid hormones (Li *et al.*, 1992a, 1992b; Vacherot *et al.*, 1995).

Pleiotrophin normally signals a diversity of responses that suggest its potential importance in dysregulated growth and angiogenesis when it is inappropriately expressed in the cancer cell. PTN has mitogenic activity for fibroblasts (Milner *et al.*, 1989), for brain capillary endothelial cells (Courty *et al.*, 1991), and for SW-13 (adrenal carcinoma) cells in soft-agar culture (Fang *et al.*, 1992). Pleiotrophin also stimulates angiogenesis *in vivo* and *in vitro* by different criteria (Courty *et al.*, 1991). Furthermore, the *Ptn* gene is a proto-oncogene; *Ptn*-transformed NIH 3T3 cells develop into rapidly growing and highly vascular tumors in flanks of nude mice (Chauhan *et al.*, 1993; Deuel *et al.*, 2002). Importantly, it is highly expressed in many human breast cancers

(Fang *et al.*, 1992; Tsutsui *et al.*, 1993). Introduction of the exogenous *Ptn* gene into premalignant SW13 (adrenal carcinoma) cells and into MCF-7 (human premalignant breast carcinoma) stimulates highly malignant subcutaneous tumor growth at sites of implantation in flanks of nude mice (Zhang and Deuel, 1999; Chang and Zuka, in press), and the highly malignant phenotype of human malignant breast cancer cells and other cells with constitutive activation of the *Ptn* gene is reversed when a dominant negative inhibitor of PTN signaling or a *Ptn* gene-targeted ribozyme is introduced (Czubayko *et al.*, 1996; Zhang and Deuel, 1999; Aigner *et al.*, 2002; Chang and Deuel, Submitted), thus establishing that a single gene mutation that initiates activation of the *Ptn* gene alone is sufficient to switch the premalignant phenotype of premalignant cells to that of a highly malignant phenotype. These findings may be highly significant, since many different human malignancies of different origins have activated endogenous *Ptn* (Mailleux *et al.*, 1992; Nakagawara *et al.*, 1995; Czubayko *et al.*, 1996; Zhang *et al.*, 1997; Weber *et al.*, 2000; Mentlein and Held-Feindt, 2002). Importantly, in those cell lines studied, expression of the endogenous *Ptn* gene is constitutive, and PTN signaling has been demonstrated to be a major contributor to the highly malignant phenotype of these cells (Mailleux *et al.*, 1992; Nakagawara *et al.*, 1995; Czubayko *et al.*, 1996; Zhang *et al.*, 1997; Weber *et al.*, 2000).

Pleiotrophin signals by inactivating the tyrosine phosphatase activity of the transmembrane receptor protein tyrosine phosphatase (RPTP) $\beta/\zeta$  (Meng *et al.*, 2000). Inactivation of RPTP $\beta/\zeta$  by the interaction of PTN and RPTP $\beta/\zeta$  leaves unchecked the persistent activity of a tyrosine kinase that phosphorylates the identical tyrosine that is dephosphorylated by RPTP $\beta/\zeta$  (Meng *et al.*, 2000). Thus, the tyrosine phosphorylation levels of the substrates of RPTP $\beta/\zeta$  are sharply increased. Pleiotrophin is the first natural ligand to be discovered for any of the RPTPs (Meng *et al.*, 2000). Anaplastic Lymphoma Kinase (ALK) also has been proposed as a receptor for PTN (Stoica *et al.*, 2001), as has syndecan 3 (Rauvala *et al.*, 2000), leaving open the place of these different proteins in PTN signaling. The downstream targets of PTN/RPTP $\beta/\zeta$  signaling pathway are  $\beta$ -catenin (Meng *et al.*, 2000),  $\beta$ -adducin (Pariser, Perez-Pinera, *et al.*, 2005), and Fyn (Pariser, Ezquerra *et al.*, 2005).  $\beta$ -catenin,  $\beta$ -adducin, and Fyn are substrates of RPTP $\beta/\zeta$ ; the steady-state levels of tyrosine phosphorylation of each of these proteins is sharply increased in PTN-stimulated cells. However, each of these proteins is phosphorylated in non-PTN-stimulated cells as well, suggesting their steady-state levels of tyrosine phosphorylation are maintained by the endogenous PTN/RPTP $\beta/\zeta$  signaling pathway. Each of the downstream targets of PTN signaling is an important regulator of cytoskeletal structure (Meng *et al.*, 2000; Pariser and Ezquerra *et al.*, 2005; Pariser and Perez-Pinera *et al.*, 2005), and destabilization of cytoskeleton and loss of cell-cell adhesion is the immediate response of cells stimulated by PTN (Meng *et al.*,

2000), suggesting that a major target of exogenous PTN is desestabilization of cytoskeletal elements and cell–cell adhesion through the coordinated increase in tyrosine phosphorylation of these substrates of RPTP $\beta$ / $\zeta$ .

Collagens and elastin are the major fibrillar elements in the cardiovascular system and thus are major determinants in vascular tone, distensibility, and other properties of aorta and other vessels. Analysis of aorta of *Ptn*  $-/-$  and *Mk*  $-/-$  mice uncovered the previously unknown but remarkable findings that PTN and MK are major regulators of the transcripts of the catecholamine biosynthesis pathway (Ezquerro *et al.*, 2004, 2006) and the transcripts of the renin–angiotensin pathway (Herradon *et al.*, 2004, 2005) in mouse. Since procollagen and elastin synthesis is known to be regulated through both the catecholamine and the angiotensin II signaling pathways, the striking down-regulation of the elastin precursor gene in aorta of *Ptn*  $-/-$  and *Mk*  $-/-$  mice define PTN and MK as critical regulators of elastin expression (Ezquerro *et al.*, Submitted). Furthermore, tumors of MMTV-PyMT transgenic mice with very high levels of the MMTV-*Ptn* transgene have strikingly increased synthesis of collagen and elastin interspersed with activated stroma and increased tumor angiogenesis which is also seen in the wound-healing process (Chang and Deuel, Submitted). These data, collectively, suggest that pleiotrophin plays an important role in the remodeling of the microenvironment of cells in both normal and disordered conditions.

## X. OTHER ROLES OF GROWTH FACTORS AND CYTOKINES

A growing appreciation for roles of growth factors in many normal and abnormal processes is emerging from numerous other investigations of a diverse nature. For example, TGF- $\alpha$  and TGF- $\beta$  are expressed with high specificity in developing mouse embryo (Twardzik, 1985; Heine *et al.*, 1987); PDGF may mediate normal gliogenesis (Richmond *et al.*, 1988); maternally encoded FGF, TGF- $\beta$ , and PDGF have been implicated as important in the developing *Xenopus* embryo (Kimelman and Kirschner, 1987;

Weeks and Melton, 1987; Mercola *et al.*, 1988); and bFGF is a potential neurotrophin during development (Anderson *et al.*, 1988). PDGF also has been identified within plaques and is a potent vasoconstrictor and thus has been implicated in the genesis of atherosclerosis (Berk *et al.*, 1986; Libby *et al.*, 1988). Furthermore, it is secreted from endothelial cells and arterial smooth muscle cells (Jaye *et al.*, 1985; Sejersen *et al.*, 1986; Martinet *et al.*, 1987; Tong *et al.*, 1987; Majesky *et al.*, 1988; Rubin *et al.*, 1988) and activated monocytes/macrophages (Martinet *et al.*, 1987). Elevated levels of PDGF receptors are found on synovial cells in patients with rheumatoid arthritis (Rubin *et al.*, 1988). In each instance, however, when the *in vitro* studies are considered in the context of roles of the growth factors in inflammation and tissue repair, it seems likely that the common roles of growth factors are associated with normal development and that the abnormal remodeling is associated with disease states, indicating the importance of attention to mechanisms that regulate cell type and temporal levels of expression of the growth factors and their cognate receptors.

## XI. CONCLUSIONS

Much needs to be learned concerning the roles of growth factors and cytokines if we are to establish fully how they function in both normal and dysregulated tissue remodeling. Remarkable progress over the past several years has resulted from the identification, isolation, cloning, and characterization of the properties of these molecules and their use in wound-healing models. The most important lesson learned from their use appears to be that the growth factors and cytokines are important to initiate and accelerate the normal processes involved in going from injury to repair. Questions for future avenues of investigation should address mechanisms by which these factors initiate and propagate the processes and the regulatory signals that govern cell type specificity, differentiation responses in cells migrating into and dividing within wounds, and the temporal sequences needed for orderly progression to a healed and ultimately functional tissue.

### I. INTRODUCTION

Tissue engineering has as its main goal the fabrication of artificial tissues for use as replacements for damaged body structures. Great advances have been made in terms of developing prosthetic devices that can repair structural defects (e.g., vascular grafts) and even replace complex mechanical behaviors (e.g., artificial joints). However, the challenge for the future is to develop tissue substitutes that restore the normal biochemical functions of living tissues in addition to their structural features. To accomplish this feat, we must first establish precise design criteria for tissue fabrication. These design features should be based on a thorough understanding of the molecular and cellular basis of tissue regulation. They also must take into account the important role that insoluble extracellular matrix (ECM) scaffolds and mechanical stresses play in control of cell phenotypes or “fates” (e.g., growth, differentiation, motility, apoptosis, different stem cell lineages) during tissue formation and repair. This latter point is critical since the spatial organization of cells and the mechanical constraints imposed on them as they grow actively regulate tissue development (Ingber, 2006a) as well as tissue and organ function throughout adult life (Ingber, 2006b).

The goal of this chapter is not to provide an extensive review of literature in the field of ECM biology or tissue development. Rather, I will summarize the known functions of ECM and describe some insights we have made relating to how ECM regulates cell growth and function as well as tissue morphogenesis. Our analysis of this regulatory mechanism should be of particular interest to the tissue engineer, because it has led to the identification of critical chemical and mechanical features of ECM that are responsible for control of cell fate switching in developing tissues. In addition, I hope to introduce the reader to some unanswered puzzles in developmental biology that, if deciphered, could provide powerful new approaches to tissue regeneration and repair.

### II. EXTRACELLULAR MATRIX STRUCTURE AND FUNCTION

#### Composition and Organization

One of the most critical elements of tissue engineering is the ability to mimic the ECM scaffolds that normally serve to organize cells into tissues. ECMs are composed of different collagen types, large glycoproteins (e.g., fibronectin, laminin, entactin, osteopontin), and proteoglycans that

contain large glycosaminoglycan side chains (e.g., heparan sulfate, chondroitin sulfate, dermatan sulfate, keratan sulfate, hyaluronic acid) (see Chapter 8, by Olsen, for more details). While all ECMs share these components, the organization, form, and mechanical properties of ECMs can vary widely in different tissues, depending on the chemical composition and three-dimensional (3D) organization of the specific ECM components that are present. For example, interstitial collagens (e.g., types I, III) self-assemble into 3D lattices, which, in turn, bind fibronectin and proteoglycans. This type of native ECM hydrogel forms the backbone of loose connective tissues, such as dermis. In contrast, basement membrane collagens (types IV, V) assemble into planar arrays; when these collagenous sheets interact with fibronectin, laminin, and heparan sulfate proteoglycan, a planar ECM results (i.e., the basement membrane). The ability of tendons to resist tension and of cartilage and bone to resist compression similarly result from local differences in the organization and composition of the ECM.

### **In Vivo Foundation for Cell Anchorage**

The first and foremost function of ECM in tissue development is its role as a physiological substratum for cell attachment. This feature is easily visualized by treating whole tissues with ECM-degrading enzymes (collagenase, proteases); cell detachment and loss of cell and tissue morphology rapidly result. Cells that are dissociated in this manner can reattach to an artificial culture substrate (e.g., plastic, glass). However, adhesion is again mediated by cell binding to ECM components that are either experimentally immobilized on the culture surface, deposited *de novo* by the adhering cells, or spontaneously adsorbed from serum (e.g., fibronectin, vitronectin) (Kleinman *et al.*, 1981; Madri and Stenn, 1982; Stenn *et al.*, 1979; Wicha *et al.*, 1979; Salomon *et al.*, 1981; Bissell *et al.*, 1986; Ingber, 1990). In fact, standard tissue culture plates are actually bacteriological (nonadhesive) plastic dishes that have been chemically treated using proprietary methods to enhance adsorption of serum- and cell-derived ECM proteins. To summarize, cells do not attach directly to the culture substrate (i.e., plastic or glass); rather, they bind to intervening ECM components that are adsorbed (or derivatized) to these substrates. For this reason, cell adhesion can be prevented by coating normally adhesive culture surfaces with polymers that prevent protein adsorption, such as poly(hydroxyethylmethacrylate) (Folkman and Moscona, 1978; Ingber, 1990).

### **Spatial Organizer of Polarized Epithelium**

Living cells exhibit polarized form as well as function (e.g., basal nuclei, supranuclear Golgi complex, apical secretory granules in secretory epithelia). Dissociated cells fail to orient in a consistent manner when cultured on standard tissue culture substrata or on interstitial connective tissue. In the case of epithelial cells, normal polarized form is often restored if the cells synthesize and accumulate their own

ECM or if they are cultured on exogenous basement membrane (i.e., the specialized epithelial ECM) (Emerman and Pitelka, 1977; Chambard *et al.*, 1981; Ingber *et al.*, 1986). These types of studies suggest that basement membrane normally serves to integrate and maintain individual cells within a polarized epithelium. Clearly, there are many intracellular and intercellular determinants of polarized cell form and function (e.g., cytoskeletal organization, organelle movement, junctional complex formation). However, anchorage to ECM appears to provide an initial point of orientation and stability on which additional steps in the epithelial organization cascade can build. ECM may regulate the orientation of other cell types (e.g., chondrocytes, osteoclasts) as well.

### **Scaffolding for Orderly Tissue Renewal**

All tissues are dynamic structures that exhibit continual turnover of all molecular and cellular components. Thus, it is the maintenance of tissue pattern integrity that is most critical to the survival of the organism, and regeneration of normal tissue architecture is one of the main goals of tissue engineering. Maintenance of specialized tissue form requires that cells lost due to injury or aging must be replaced in an organized fashion. Importantly, orderly tissue renewal depends on the continued presence of insoluble ECM scaffoldings, which act as templates that maintain the original architectural form and ensure accurate regeneration of pre-existing structures (Vracko, 1974). For example, when cells within a tissue are killed by freezing or treatment with toxic chemicals, all of the cellular components die and are removed; however, the basement membranes often remain intact. These residual ECM scaffoldings ensure correct repositioning of cells (e.g., cell polarity) and restore different cell types to their correct locations (e.g., muscle cells within muscle basement membrane, nerve cells in nerve sheaths, endothelium within vessels) in addition to promoting the cell migration and growth that are required for repair of all the component tissues. Conversely, loss of ECM integrity during wound healing results in disorganization of tissue pattern and, thus, scar formation. Uncoupling between basement membrane extension and cell doubling also leads to disorganization of tissue morphology during neoplastic transformation (Ingber *et al.*, 1981).

### **Establishment of Tissue Microenvironments**

ECMs often establish a physical boundary between neighboring tissues. For example, the basement membrane normally restricts mixing between the epithelium and underlying connective tissue, and compromise of basement membrane integrity is indicative of the onset of malignant invasion when seen in the context of tumor formation (Ingber *et al.*, 1981). The ECM boundary also may regulate macromolecular transport between adjacent tissues, given that the basement membrane forms the semipermeable filtration barrier in the kidney glomerulus (Farquhar, 1978).

However, little is known about this potential function of the ECM in other local tissue microenvironments.

### Sequestration, Storage, and Presentation of Soluble Regulatory Molecules

ECMs may modulate tissue growth and morphogenesis through their ability to bind, store, and eventually release soluble regulators of morphogenesis. For example, the soluble mitogen, basic fibroblast growth factor (FGF) exists in an immobilized form in ECMs deposited by cells cultured *in vitro* (Vlodavsky *et al.*, 1987) as well as in normal tissues (e.g., corneal basement membranes) *in vivo* (Folkman *et al.*, 1988). In fact, many cytokines (e.g., FGF, VEGF, HGF, insulin-like growth factor, hematopoietic growth factors) are normally stored bound to heparin, heparan sulfate, or some other specific binding proteins within natural ECMs (Gordon, 1991; Folkman and Shing, 1992). The low growth rate observed in most normal tissues may result from sequestration of mitogens by ECM, whereas release of these stored factors (*stormones*) due to injury or hormonally-induced changes in ECM turnover may help to switch growth on locally. Binding of other types of regulatory molecules to the endothelial basement membrane (e.g., plasminogen activator inhibitor; Pollanen *et al.*, 1987) also may play a role in tissue physiology (e.g., blood coagulation, cell migration).

### Regulator of Cell Growth, Differentiation, and Apoptosis

Most normal (nontransformed) cells grow only when attached and spread on a solid substrate (Folkman and Moscona, 1978). Cells attach and spread *in vitro* either by depositing new ECM components or by binding to exogenous ECM (Kleinman *et al.*, 1981; Madri and Stenn, 1982; Stenn *et al.*, 1979; Wicha *et al.*, 1979; Salomon *et al.*, 1981; Bissell *et al.*, 1986; Ingber, 1990). In fact, cell spreading and growth can be suppressed by inhibiting ECM deposition *in vitro* using drugs (Madri and Stenn, 1982; Stenn *et al.*, 1979; Wicha *et al.*, 1979). Cell growth stimulated by soluble mitogens also has been shown to vary, depending on the type of ECM component used for cell attachment (e.g., collagen versus fibronectin; Kleinman *et al.*, 1981; Bissell *et al.*, 1986; Ingber *et al.*, 1987) as well as on the mechanical properties of the ECM (e.g., malleable gel versus rigid ECM-coated dish; Li *et al.*, 1987; Kubota *et al.*, 1987; Ben Ze'ev *et al.*, 1988; Opas, 1989; Vernon *et al.*, 1992).

Interestingly, ECM substrates that promote growth tend to suppress differentiation, and vice versa. For example, many cells proliferate and lose differentiated features when cultured on attached type I collagen gels that can resist cell tension and promote cell spreading. In contrast, the same cells cease growing and increase expression of tissue-specific functions (e.g., albumin secretion in hepatocytes, milk secretion and acinus formation by mammary cells, capillary tube formation by endothelial cells) if cultured on the same gels

that are made flexible by floating them free in medium or on attached ECM gels that exhibit high malleability (e.g., basement membrane gels, such as Matrigel). Under these conditions, the cells exert tension across their adhesions, resulting in contraction of the ECM gel and cell rounding, which, in turn, shut off growth and turn on differentiation-specific gene functions. The differentiation-inducing effects of these malleable ECM substrates also can be suppressed by making the gels rigid through chemical fixation (Li *et al.*, 1987; Opas, 1989), thus confirming the critical role of cell-generated mechanical forces in this response.

While local changes in ECM turnover may promote tissue remodeling, large-scale breakdown of the ECM may force the same growing tissues to undergo involution. Many cultured cells rapidly lose viability and undergo programmed cell death (i.e., apoptosis) when detached from ECM and maintained in a round form (Meredith *et al.*, 1993; Chen *et al.*, 1997). Loss of basement membrane integrity is also observed in regions of tissues that are actively regressing (Trelstad *et al.*, 1982; Ingber *et al.*, 1986), and growing tissues (e.g., capillaries, mammary gland) can be induced to involute using pharmacological agents (e.g., proline analogs) that inhibit ECM deposition and lead to basement membrane dissolution *in vivo* (Ingber *et al.*, 1986; Wicha *et al.*, 1980; Ingber and Folkman, 1988). Recent transgenic mice studies confirm that growing tissues can be made to involute by shifting the endogenous proteolytic balance such that total ECM breakdown results (Talhouk *et al.*, 1992). These findings suggest that local changes in ECM composition and flexibility may regulate cell sensitivity to soluble mitogens and thereby control cell growth, viability, and function in the local tissue microenvironment.

## III. PATTERN FORMATION THROUGH ECM REMODELING

### Mesenchymal Control of Epithelial Pattern

Probably the greatest insight into the role of ECM in tissue development comes from analysis of embryogenesis. In the embryo, genesis of a tissue's characteristic form (e.g., tubular versus acinar) and deposition of ECM are both controlled by complex interactions between adjacent epithelial and mesenchymal cell societies. The epithelial cell is genetically programmed to express tissue-specific (differentiated) functions and to deposit the insoluble basement membrane, which functions as a common attachment foundation that both separates adjacent tissues and stabilizes tissue form (Banerjee *et al.*, 1977; Dodson and Hay, 1971). However, while production of tissue-specific cell products (cytodifferentiation) is determined by the epithelium, tissue pattern (histodifferentiation) is usually directed by the surrounding mesenchyme. For example, when embryonic mammary epithelium is isolated and combined with salivary mesenchyme, the mammary epithelial cells take on the form of the salivary gland, although they still produce milk proteins

(Sakakura *et al.*, 1976). However, the specificity of these epithelial–mesenchymal interactions can vary widely from organ to organ. For instance, embryonic salivary epithelia specifically require salivary mesenchyme for successful development, while pancreatic epithelia will undergo normal cytodifferentiation and histodifferentiation in response to mesenchyme isolated from a variety of embryonic tissues (Golosow and Grobstein, 1962).

### Tissue Patterning Through Localized ECM Remodeling

The complex tissue patterns generated through epithelial–mesenchymal interactions result from the establishment of local differentials in tissue growth and expansion in a microenvironment that is likely saturated with soluble mitogens. The classic work on salivary gland development by Bernfield and coworkers revealed that the epithelium imposes morphological stability through production of its basement membrane, whereas the mesenchyme produces local changes in tissue form, specifically by degrading basement membrane at selective sites (Banerjee *et al.*, 1977; Bernfield and Banerjee, 1978; Smith and Bernfield, 1982; Bernfield *et al.*, 1972; David and Bernfield, 1979). An increased rate of cell division is observed in the tips of growing lobules, where the highest rate of ECM breakdown and resynthesis (i.e., highest turnover rate) is also observed. At the same time, the mesenchyme slows basement membrane turnover and suppresses epithelial cell growth in the clefts of the glands. This is accomplished by secretion of fibrillar collagens that slow ECM degradation locally and thereby promote basement membrane accumulation in these regions. Similar local coupling between ECM turnover, cell growth rates, and tissue expansion is observed in many other developing tissues, including growing capillary blood vessels (Folkman, 1982).

It is important to note that increased ECM turnover involves enhanced rates of matrix synthesis as well as degradation. In fact, net basement membrane accumulation (i.e., increased area available for cell attachment) must result for epithelial tissues to grow and expand laterally; thus, the local rate of ECM synthesis must be greater than that of degradation in these high-turnover regions. If the rate of ECM degradation is significantly greater than the rate of synthesis, then net basement membrane dissolution along with cell retraction and rounding result. As described earlier, this would lead to cell death and tissue regression rather than expansion.

### Role of Mechanical Stresses

Before ending discussion of the role of ECM in pattern formation, it is critical to emphasize that while chemical regulators mediate tissue morphogenesis, the signals that are actually responsible for dictating tissue pattern are often mechanical in nature (Ingber, 2006b). The pattern-generating effects of compression on bone, shear on blood

vessels, and tension on muscle are just a few examples. Mechanical stresses are also important for embryological development; however, internal cell-generated forces appear to play a more critical role (Ingber, 2006a). For example, mechanical tension that is generated via actomyosin filament sliding within the cytoskeleton of the cells that compose the embryo play a key role during gastrulation (Beloussov *et al.*, 1975) as well as during tissue morphogenesis (Ash *et al.*, 1973). In fact, the pattern of development can be experimentally altered by applying external stresses to the embryo using micropipettes (Beloussov *et al.*, 1988). Tensile forces that are generated internally within mesenchyme and transmitted across ECM are also likely required for the condensation of mesenchyme that commonly precedes formation of new organ rudiments. The pattern-generating capabilities of mesenchyme isolated from different developing tissues also correlates with differences in their ability to exert mechanical tension on external substrates (e.g., Nogawa and Nakanishi, 1987). Local changes in ECM turnover may drive morphogenetic patterning of tissues, in part by altering the mechanical compliance of the ECM and thereby changing cell shape or cytoskeletal tension (Ingber and Jamieson, 1985; Huang and Ingber, 1999), as is described next.

## IV. MECHANOCHEMICAL SWITCHING BETWEEN CELL FATES

Given the pivotal role that ECM plays in tissue development, many studies have been carried out to analyze how changes in cell–ECM interactions act locally to regulate cell sensitivity to soluble mitogens and thereby establish the differentials of growth, differentiation, apoptosis, and motility that are required for tissue morphogenesis. To accomplish this, simplified *in vitro* model systems have been developed that retain the minimal determinants necessary for maintenance of the physiological functions of interest (i.e., cell growth and differentiation) (Ingber, 1990; Ingber and Folkman, 1989; Mooney *et al.*, 1992). For example, to determine the effects of varying cell–ECM contacts directly, we precoated bacteriological petri dishes that were otherwise nonadhesive with different densities of purified ECM molecules, such as fibronectin, laminin, or different collagen types. Quiescent, serum-deprived cells were plated on these dishes in chemically defined medium that contained a constant and saturating amount of soluble growth factor.

When capillary endothelial cells were studied, DNA synthesis and cell-doubling rates increased in an exponential fashion as the density of immobilized ECM ligand was raised and cell spreading was promoted (Ingber and Folkman, 1989; Ingber, 1990). When higher cell-plating numbers were used to promote cell–cell interactions as well as cell–ECM contact formation, the capillary cells could be switched between growth and differentiation (capillary tube formation) in the presence of saturating amounts of soluble

mitogen (FGF) simply by varying the ECM coating density (Ingber and Folkman, 1989). Specifically, when plated on a high ECM density (e.g.,  $>500$  ng/cm<sup>2</sup> fibronectin), the cells attached, spread extensively, formed many cell–cell contacts, and organized into a planar cell monolayer. When the same cells were plated on a low ECM density ( $<100$  ng/cm<sup>2</sup>), the cells attached but could not spread, and thus only cell clumps or aggregates were observed. When the same capillary cells were plated on a moderate density, cells first attached, spread, and formed cell–cell contacts, as they did on the higher ECM densities. However, the tensile forces generated by the cells appeared to overcome the resistance provided by their relatively weak ECM adhesions, and thus the cell aggregates began to retract over a period of hours until a mechanical equilibrium was attained. Under these conditions, formation of an extensive network comprising interconnected capillary tubes resulted. Many of these capillary tubes became elevated above the culture surface, although the network remained adherent to the culture dish at discrete points through interconnected multicellular aggregates. The importance of mechanical forces for this switching between growth and differentiation was confirmed by demonstrating that similar capillary tube formation could be induced on the high ECM density that normally promoted spreading and growth simply by increasing the cell-plating numbers and thereby amplifying the level of cell tension.

The same system was used to demonstrate similar shape- (stretch-) dependent switching between growth and differentiation in other cell types. For example, the growth and differentiation of primary rat hepatocytes could be controlled independent of cell–cell contact formation by varying cell–ECM contacts and cell spreading using the method described earlier (Mooney *et al.*, 1992). Additional studies confirmed that ECM exerts its regulatory effects at the level of gene expression (Mooney *et al.*, 1992; Hansen *et al.*, 1994) and that these effects are mediated at least in part through modulation of the cytoskeleton (Mooney *et al.*, 1995). These results are consistent with those from other laboratories, which demonstrate that malleable ECM gels (e.g., Matrigel, native collagen gels) that promote cell rounding also induce differentiation and suppress growth, whereas the opposite effects are produced when these gels are fixed and made rigid (Li *et al.*, 1987; Kubota *et al.*, 1987; Ben Ze'ev *et al.*, 1988; Opas, 1989).

Altering cell–ECM contacts by varying ECM coating densities influences cell function via two distinct, but integrated, mechanisms. First, increasing the local density of immobilized ECM ligand promotes clustering of transmembrane ECM receptors on the cell surface, which are known as *integrins* (Hynes, 1987). Integrin clustering, in turn, activates a number of different chemical signaling pathways (e.g., tyrosine phosphorylation, inositol lipid turnover, Na<sup>+</sup>/H<sup>+</sup> exchange, MAP kinase) that are also utilized by growth factor receptors to alter cellular biochemistry and gene

expression (Ingber *et al.*, 1990; Schwartz *et al.*, 1991; McNamee *et al.*, 1993; Plopper *et al.*, 1995; Geiger *et al.*, 2001). Activation of these signaling pathways likely plays an important role in control of cell differentiation and survival; however, integrin-dependent chemical signaling alone is not sufficient to explain how cells are induced to enter S phase and proliferate (Ingber, 1990; Hansen *et al.*, 1994; Chen *et al.*, 1997; Huang *et al.*, 1998; Mammoto *et al.*, 2004). A second mechanism that involves tension-dependent changes in cell shape and cytoskeletal organization or changes in the level prestress (isometric tension) within the cell and linked ECM also comes into play.

The importance of tension-dependent changes of cell shape and cytoskeletal organization was demonstrated directly by developing a model system in which cell distortion was varied independent of the local density of immobilized ECM molecule by controlling the spatial distribution of ECM anchors that can resist cell-generated traction forces. This was made possible by adapting a technique for forming spontaneously assembled monolayers (SAMs) of alkanethiols (Prime and Whitesides, 1991) to create micropatterned surfaces containing adhesive ECM islands with defined surface chemistry, shape, and position on the cell (micrometer) scale, separated by nonadhesive regions (Singhvi *et al.*, 1994; Chen *et al.*, 1997). The method involves fabrication of a flexible elastomeric stamp that exhibits the particular surface features of interest using photolithographic techniques. The topographic high points on the stamp (e.g.,  $40 \times 40$ - $\mu$ m square plateaus raised above recessed intervening regions) are coated with an alkanethiol ink, and the stamp is then apposed to a gold-coated surface. The alkanethiol forms SAMs covering only the regions where the stamp contacts the surface (i.e.,  $40 \times 40$ - $\mu$ m squares). Then the surrounding uncoated regions are filled with a SAM composed of similar alkanethiols that are conjugated to poly(ethylene glycol) (PEG), which prevents protein adsorption. The result is a chemically defined culture surface that is completely covered with a continuous SAM of alkanethiols; however, the local adhesive islands of defined geometry support protein adsorption, whereas the surrounding boundary regions coated with PEG do not. Thus, when these substrates are coated with a high density of purified ECM protein, such as laminin or fibronectin, adhesive islands of defined shape and position coated with a saturating density of matrix molecule result. Using this technique, cell position and shape can be precisely controlled because the cells only attach to the ECM-coated adhesive islands. In fact, even square and rectangular-shaped cells exhibiting 90° corners can be engineered using this approach (Singhvi *et al.*, 1994; Chen *et al.*, 1997).

This micropatterning method was first used to ask the following question: If cells are restricted to a small size similar to that produced on a low ECM coating concentration but the local density of immobilized integrin ligand is increased 1000-fold, which is the critical determinant of cell

function — the ECM density or cell shape? The answer was cell shape. Primary hepatocytes remained quiescent on small adhesive islands coated with a high ECM density, even though the cells were stimulated with high concentrations of soluble growth factors, and cell growth (DNA synthesis) increased in parallel as the size of the adhesive island was increased (Singhvi *et al.*, 1994). Similar results were obtained with capillary endothelial cells (Chen *et al.*, 1997). Moreover, inhibition of hepatocyte growth on the small islands was accompanied by a concomitant increase in albumin secretion. In the case of endothelial cells, the cells were similarly induced to differentiate into capillary tubes when cultured on linear patterns that supported cell–cell contact as well as a moderate degree of cell distension, whereas the cells were induced to undergo apoptosis (cellular suicide) when cultured on the smallest islands, which fully prevented cell extension (Chen *et al.*, 1997; Dike *et al.*, 1999). Thus, cell shape and function can be engineered simply by altering the geometry of the cell's adhesive substrate.

Intracellular signals elicited by integrin receptor clustering due to ECM binding have been shown to be critical for control of cell growth and function (Hynes, 1987; Ingber *et al.*, 1990; Schwartz *et al.*, 1991; Geiger *et al.*, 2001). Thus, one could argue that cell shape and mechanical distortion of the CSK are not important. Instead, it might be the increase in the total area of cell–ECM contacts and the associated enhancement of integrin binding that dictate whether cells will grow, differentiate, or die on large versus small adhesive islands. To explore this further, substrates were designed in which a single small adhesive island (which would not support spreading or growth) was effectively broken up into many smaller islands (3–5  $\mu\text{m}$  in diameter) that were separated by nonadhesive barrier regions (Chen *et al.*, 1997). When capillary cells were plated on these substrates, their processes stretched from island to island and the cells exhibited an overall extended form similar to cells on large islands. However, the total area of cell–ECM contact was almost identical to that exhibited by nongrowing cells on the smaller islands. These studies revealed that in the presence of optimal growth factors and high ECM binding, DNA synthesis was high in the cells that spread over multiple small islands, whereas apoptosis was completely shut off (Chen *et al.*, 1997), thus confirming that cell shape distortion is the critical governor of this response.

Importantly, cell distortion also impacts cell migration as well as stem cell lineage switching. For instance, when cells on square islands are stimulated with motility factors, the cells preferentially extend new motile processes (e.g., lamellipodia, filopodia, microspikes) from their corners, whereas they extend in all directions along the edge of round cells on circular islands (Parker *et al.*, 2002). Cells on polygonal ECM islands also prefer to form new lamellipodia from corners with acute angles rather than obtuse angles (Brock *et al.*, 2003). In contrast, when mesenchymal stem cells are cultured on different-size ECM islands, those on small

islands switch on the fat cell lineage, whereas the spread cells on larger ECM islands become bone cells (McBeath *et al.*, 2004). Thus, taken together, these results suggest that microfabrication methods might lead to new approaches to tissue engineering using microfabricated substrates. With this approach, it may be possible to direct cell migration, growth, and differentiation of stem cells in specific locations by modifying the surface chemistry and topography of artificial materials, instead of creating gradients of soluble chemokines.

The effects of shape distortion on cell fate switching may, in part, be mediated by changes in the level of isometric tension or prestress within the cytoskeleton. For example, both flexible and poorly adhesive culture dishes that inhibit growth and induce differentiation dissipate prestress, whereas substrates that stimulate cell spreading and growth (e.g., rigid dishes) support high levels of cytoskeletal tension. Small ECM islands, which inhibit cell spreading, also prevent pulmonary vascular smooth muscle cells from responding to vasoconstrictors, such as endothelin-1 (as measured by increases of myosin light-chain phosphorylation), and similar effects are produced by culturing cells on flexible ECM substrates that dissipate tensional prestress in the ECM and in the interconnect cytoskeleton (i.e., linked through transmembrane integrins) (Polte *et al.*, 2004; Kumar *et al.*, 2006). In addition, cells preferentially differentiate on ECM substrates that are compliance matched with their cytoskeleton and that have a mechanical stiffness similar to that of their natural tissues (Griffen *et al.*, 2004; Engler *et al.*, 2004; Georges and Janmey, 2005). Cells also migrate up gradients of ECM stiffness, a process known as *durotaxis* (Lo *et al.*, 2000). These observations suggest that tissue formation may be controlled by changing the physical properties of either the ECM or the cell or by altering tension generation in the cytoskeleton.

Regional variations of cell shape distortion or of cytoskeletal prestress may similarly drive tissue patterning in the embryo. For example, during tissue morphogenesis, only a subset of cells must respond to soluble growth factors by proliferating locally and sprouting or budding outward relative to neighboring nongrowing cells. This process is repeated along the sides of the newly formed sprouts and buds, and the whole process reiterates over time; this is how the fractal-like patterns of tissues develop. This process is mediated by regional changes in ECM structure: The ECM thins in regions where new buds or sprouts will form due to local enzymatic degradation (Bernfield and Banerjee, 1978). Because tissues are prestressed (due to the action of cytoskeletal contractile forces), a local region of the tensed ECM may thin more than the rest, like a run in a woman's stocking. Cells anchored to this region will also stretch or spread, whereas the shape of neighboring cells on intact ECM would remain unchanged. If cell spreading promotes growth, then local cell growth differentials would result.

This possibility, that tissue morphogenesis may be controlled through changes in the mechanical force balance between the cytoskeleton and the ECM, is supported by recent experimental studies in embryonic systems. Analysis of the effects of cell shape on cell cycle progression *in vitro* have revealed that these effects are mediated by altering signal transduction through the small GTPase Rho and its downstream target, Rho-associated kinase (ROCK), which controls cytoskeletal tension generation (Huang *et al.*, 1998; Mammoto *et al.*, 2004). Importantly, when cytoskeletal contractility was suppressed in whole embryonic lung rudiments by inhibiting Rho or ROCK, both epithelial branching morphogenesis and angiogenesis were inhibited, and this was accompanied by decreased basement thinning (as if there was no tension in the stocking) (Moore *et al.*, 2005). In contrast, stimulating the Rho pathway had the opposite effect (i.e., it increased morphogenetic branching) at moderate levels of activation and caused complete organ contraction and inhibition of tissue growth at very high levels of stimulation (Moore *et al.*, 2005). Thus, local changes in ECM structure and cell shape caused by altering cytoskeletal prestress may govern how individual cells respond to chemical signals in their microenvironment *in vivo*, just as experimental studies using microfabricated ECM islands have demonstrated *in vitro*. This mechanism for establishing local growth differentials may play a critical role in morphogenesis in all developing systems (Ingber and Jamieson, 1985; Huang and Ingber, 1999).

## V. SUMMARY

In summary, our work has shown that the development of functional tissues, such as branching capillary networks, requires both soluble growth factors and insoluble ECM molecules. The ECM appears to be the dominant regulator, however, since it dictates whether individual cells will either proliferate, differentiate, undergo directional motility, or die locally in response to soluble stimuli. This local control mechanism is likely critical for the establishment of the local differentials of cell growth, motility, differentiation, apoptosis, and stem cell commitment that mediate pattern formation in all developing tissues.

Analysis of the molecular basis of these effects revealed that ECM molecules alter cell growth via both biochemical and biomechanical signaling mechanisms. ECM molecules cluster specific integrin receptors on the cell surface and thereby activate intracellular chemical signaling pathways (Ingber *et al.*, 1990; Schwartz *et al.*, 1991; McNamee *et al.*, 1993; Plopper *et al.*, 1995), stimulate expression of early growth response genes (e.g., c-fos, jun-B) (Hansen *et al.*, 1994), and induce quiescent cells to pass through the G<sub>0</sub>/G<sub>1</sub> transition. However, in addition, the immobilized ECM components must physically resist cell tension and promote changes of cell shape (Ingber, 1990; Ingber and Folkman, 1989; Mooney *et al.*, 1992; Singhvi *et al.*, 1994; Chen *et al.*, 1997) and cytoskeletal tension (Mooney *et al.*,

1995; Huang *et al.*, 1998; Ingber *et al.*, 1995; Mammoto *et al.*, 2004) in order to promote full progression through G<sub>1</sub> and entry into S phase. In fact, studies with living and membrane-permeabilized cells confirm that changes in cell shape result from the action of mechanical tension generated within microfilaments and balanced by resistance sites within the underlying ECM (Sims *et al.*, 1992; Kumar *et al.*, 2006). Local changes of ECM structure or mechanics will therefore alter the ECM's ability to resist cell tractional forces exerted on integrins and thereby produce changes in cytoskeletal organization. This will, in turn, alter the level of isometric tension (prestress) in the cytoskeleton as well as modulate the activity of various signal transduction pathways inside the cell (Ingber, 2006). Taken together, this work suggests that the pattern-regulating information ECM conveys to cells is both chemical and mechanical in nature. Thus, design of future artificial ECMs for tissue-engineering applications must take into account both of these features.

## VI. THE FUTURE

Early tissue-engineering efforts by reconstructive surgeons and material scientists started with knowledge of the clinical need and of the mechanical behavior of connective tissues on the macroscopic scale and worked backwards. The long-term goal for the field is to design and fabricate tissue substitutes starting from first principles. This includes incorporating biologically inspired mechanical and architectural principles as well as an in-depth understanding of the molecular and biophysical basis of tissue regulation. Clearly, given the potent and varied functions of the ECM and fabrication of artificial ECMs will play a central role in all of these future efforts. We and others have already begun to explore the utility of synthetic bioerodible polymers as cell attachment substrates (Cima *et al.*, 1991; Mikos *et al.*, 1993) and the potential usefulness of immobilized synthetic ECM peptides for controlling cell growth and function (Hansen *et al.*, 1994; Mooney *et al.*, 1992; Roberts *et al.*, 1998). These materials offer a major advantage in terms of biocompatibility, since the artificial substrates completely disappear over time, and thus the implanted donor cells become fully incorporated into the host. They also provide great chemical versatility as well as the potential for large-scale production at relatively low cost. In addition, use of synthetic chemistry reduces the likelihood of batch-to-batch variation during large-scale production, a problem that can potentially complicate use of purified ECM components. For these reasons, polymer chemistry and novel fabrication techniques will likely lead to development of more effective tissue substitutes.

However, if we understood the fundamental principles that guide ECM remodeling and pattern formation in tissues, perhaps tissue engineering might take a different approach in the future. For example, one could envision entirely new methods of clinical intervention if we understood how

tissue-specific mesenchyme generates tissue pattern; how ECM turnover is controlled *locally*; how cell-generated contractile forces contribute to tissue repair and remodeling; or how compressing or pulling tissues alter their growth and form. This knowledge could lead to methods for identifying and isolating relevant pattern-generating cells; for developing pharmacological modifiers of ECM remodeling that

may be incorporated in local regions of implants to promote or suppress tissue expansion locally; and for fabricating biomimetic scaffolds that mimic the mechanical and architectural features of natural ECMs necessary to switch on or off the function of interest (e.g., growth vs. differentiation or apoptosis) at a particular time or place. These are just a few of the challenges for the future.

## VII. ACKNOWLEDGMENTS

I would like to acknowledge that the success of many of the studies summarized would not have been possible without the assistance of my major collaborators, including Drs. Judah Folkman, Robert Langer, Martin Schwartz, Jay Vacanti,

and George Whitesides, and the multiple students and post-doctoral fellows who executed these experiments in our laboratories. This work was supported by grants from NIH, NASA, DARPA, ARO, and NSF.

### I. INTRODUCTION

With increasing fetal development, the mechanism of mammalian wound healing transitions from regeneration to a repair process characterized by organized wound contraction and scar synthesis. Recently, a variety of tissue engineering constructs have been developed to block the contraction and scar formation mechanisms of repair and induce regeneration following injury. Such constructs, mostly scaffolds that are analogs of extracellular matrix and possess specific biological activity, have become the basis of studies of *in vivo* synthesis of tissues and organs. In this article, we provide an overview of mammalian wound healing processes following severe injury as well as a description of the tissue triad and the regenerative capacity of the three distinct tissue types that comprise the triad. We also discuss the critical structural elements of an active extracellular matrix analog that induces regeneration, and describe the use of standardized wound models for study of *in vivo* regeneration processes. We conclude this review describing recent data from studies utilizing active extracellular matrix analogs (scaffolds) that have shown regenerative activity.

The goal of achieving *in vivo* induced regeneration for a variety of tissue and organs following severe injury remains

at the forefront of current tissue engineering investigations. Typically, an analog of the extracellular matrix is utilized as a template that, when properly formulated, induces regeneration of lost or damaged tissue. Currently, successful regeneration has been induced in the skin and peripheral nerves (Yannas, 2001), while progress has been made in developing appropriate extracellular matrix analogs to alter the typical organismic response to injury in a variety of tissues, including kidney, cartilage, bone, central nervous system, and brain dura. These investigations, active since the mid-1970s, have focused primarily on identifying the optimal extracellular matrix analog components to block organized wound contraction and scar tissue formation while inducing regeneration of physiological tissue (Yannas, 2001). Although many tissue engineering investigations currently focus on developing techniques appropriate for synthesis of tissues and organs *in vitro*, such products must eventually be implanted in the appropriate anatomical site of the host. Since implantation of an organ construct is almost always preceded by a surgical procedure that generates a severe wound, it is essential to master the evolving methodology of *in vivo* wound healing in order to synthesize appropriate neo-organ constructs *in vitro* for eventual implantation. The goal of this chapter is to inform the reader

about the salient features of the organismic response to injury, the historical underpinnings of current studies of induced tissue regeneration, induced tissue regeneration as a technique to treat severe injuries to a variety of tissue and organs, and the future directions of research in this field.

## II. MAMMALIAN RESPONSE TO INJURY

### Defect Scale

Treatment options for organ injury depend significantly on the scale of the defect. Microscopic defects can be treated using a wide variety of soluble factors (i.e., herbs, potions, pharmaceuticals, vitamins, hormones, and antibiotics). However, organ-scale defects present a significantly larger wound site, require considerably different treatment practices, and constitute the focus of this chapter. These defects, created primarily by disease or by an acute or chronic insult that results in millimeter- or centimeter-scale wounds, cannot be treated with drugs because the problem is the failure of a mass of tissue, including cells, soluble proteins and cytokines, and insoluble extracellular matrix (ECM). Significant loss of function in the affected tissue or organ, termed the *missing organ*, leads to consequences such as lack of social acceptance in cases of severe burns and facial scars, loss of mobility and sensory function in the case of neuroma, and life-threatening symptoms in cases such as cirrhotic liver, large-scale severe burns, and ischemic heart muscle.

### Regeneration versus Repair

Certain organisms have the ability to regenerate significant portions of damaged tissue. An example is the amphibian newt, which regenerates functional limbs following amputation. The mammalian fetus has displayed the ability to regenerate damaged organs and tissue spontaneously up to the third trimester of gestation; however, adult mammals do not typically exhibit spontaneous regeneration following severe organ injuries (Mast *et al.*, 1992; Yannas, 2001). Instead, the adult mammal response to severe injury is closure of the wound by contraction and scar tissue formation, a process termed *repair*. Cell-mediated contraction of the wound site is observed in many different species, to varying degrees, at many organ sites (Yannas, 2001). Distinct from repair, *regeneration* is characterized by synthesis of a physiological (normal, functional) replacement tissue in the wound site that is structurally and functionally similar to the original tissue. Based on these observations, for the remainder of this chapter, *early fetal* refers to the fetal response to injury that leads to regeneration, while *adult* refers to all mammals (adult as well as late fetal) that respond to injury via repair.

The contractile fibroblast phenotype, termed the *myofibroblast*, plays a critical role in determining the nature (repair or regeneration) of mammalian wound healing. During adult repair, myofibroblast-mediated organized wound contraction and scar tissue synthesis is observed

(Yannas, 2001). During early fetal healing, differentiation of myofibroblasts has not yet occurred, and regeneration of damaged tissue and organs occurs in the absence of contraction. The data suggest that induced organ regeneration in the adult may be encouraged by developing techniques to stimulate partial reversion to early fetal healing. Additionally, the transforming growth factor- $\beta$  (TGF- $\beta$ ) family of molecules has been implicated in this ontogenetic transition between fetal regeneration and adult repair response to injury. TGF- $\beta$ s are multifunctional cytokines with widespread effects on cell growth and differentiation, embryogenesis, immune regulation, inflammation, and wound healing (Border *et al.*, 1995). In terms of their relationship with repair processes, TGF- $\beta$ 1 and TGF- $\beta$ 2 are known to promote scar, while TGF- $\beta$ 3 may reduce scar (Lin *et al.*, 1995; Shah *et al.*, 1995). As such, deficient levels of TGF- $\beta$ 1 and - $\beta$ 2 and increased levels of TGF- $\beta$ 3 are observed in early-gestational (“fetal” regenerative healing response) compared to late-gestational (“adult” repair healing response) mice. These results implicate increased TGF- $\beta$ 1, - $\beta$ 2, and decreased TGF- $\beta$ 3 expression along with myofibroblast activity in late gestation and postpartum fetal scar formation (Soo *et al.*, 2003). The available evidence suggests future experiments utilizing procedures for control of TGF- $\beta$  in conjunction with other tissue-engineering constructs that modify myofibroblast behavior, such as bioactive scaffolds, to induce regeneration of tissues that are known to be nonregenerative.

### Tissue Triad

There are three distinct tissue types, termed the *tissue triad*, which together define the structure of most organs: the epithelial layer, the basement membrane layer, and the stroma (Fig. 16.1) (Martinez-Hernandez, 1988; Yannas, 2001). Developmental and functional similarities between this triad in a variety of tissues and organs, such as skin and peripheral nerves, have been observed, suggesting that it can be used as an illustrative device to understand injury response in other organs as well (Yannas, 2001). A layer of epithelial cells (the *epithelial layer*) covers all surfaces, tubes, and cavities of the body. This layer is cell continuous and avascular. Unlike the basement membrane and stroma, the epithelial layer does not comprise a significant amount of extracellular matrix (ECM). The *basement membrane* is an acellular, avascular, continuous layer of ECM components separating the epithelial layer and the stroma. The *stroma* is cellular, contains ECM and connective tissue components, is heavily vascularized, and provides a reservoir for nutrient uptake to and waste removal from the basement membrane and epithelia.

Following injury to a variety of tissues, such as the skin, peripheral nerves, blood vessels, lung, kidney, and pancreas, the epithelial and basement membrane layers regenerate spontaneously when the stroma remains intact, while the damaged stroma heals through repair-mediated contraction and scar formation processes (Fu and Gordon, 1997;

**FIG. 16.1.** Schematics of the tissue triad structure observed in mammalian tissue. *Top:* Tissue triad of skin and peripheral nerves. The basement membrane is a thin extracellular matrix tissue located between the cellular and nonvascular epithelia (epidermis, myelin sheath) and the cellular, vascularized stroma (dermis, endoneurium). *Bottom:* Diagram of the distribution of epithelial, basement membrane, and stromal tissues in the mammalian system. Examples of stromal tissues are bone, cartilage, and their associated cell types as well as elastin and collagen. Examples of epithelial tissues are those covering the surface of the genitourinary, respiratory, and gastrointestinal tracts as well as surfaces of the mesothelial cells in body cavities, muscle fibers, fat cells, and endothelial cells in the cardiovascular system (Yannas, 2001).

Yannas, 2001; Yannas *et al.*, 1989). Understanding the injury response of the tissue triad has suggested a paradigm for inducing regeneration in nonregenerative tissues: repair mechanisms appear to be activated by disruption of the stromal architecture, and proper replacement of the stromal layer is critical for any regeneration to occur. As such, development of materials to act as analogs of the ECM to replace the lost stromal architecture has been a primary focus of studies of regenerative medicine since the mid-1980s.

### III. METHODS TO TREAT LOSS OF ORGAN FUNCTION

Six approaches have been used to restore some level of functionality to a damaged tissue or organ: transplantation, autografting, implantation of a permanent prosthetic device,

use of stem cells, *in vitro* synthesis of organs, and induced regeneration. The last three techniques are often collectively referred to as *tissue engineering* (Lanza *et al.*, 1997). *In vivo* induced regeneration is the only methodology to date that has modified the adult mammalian wound-healing response to induce regeneration. All six techniques are briefly discussed in the following sections; a more detailed description has been previously published (Yannas, 2001).

#### Transplantation

Transplantation is widely used to replace complex tissues and organs, but it is limited by two significant factors. While transplantation of a select few tissues, such as the eye and testis, occur without rejection, a significant challenge facing transplantation is the immunological barrier between

the donor and the host. After transplantation, the donor organ is attacked and rejected by the host's immune system. The primary clinical method for preventing such rejection is the use of immunosuppressive drugs for the remainder of the host's life to suppress the immune system. However, immunosuppression also makes the host vulnerable to infections (Wickelgren, 1996). A second major obstacle is the difficulty in finding immunocompatible donors and the shortness of supply of suitable organs (Lanza *et al.*, 1997).

### Autografting

With autografting, the donor and the recipient are the same individual. A fraction of the tissue or organ is harvested from an uninjured site and grafted at the nonfunctional site (Medawar, 1944). Autografting removes issues related to immune response, but it necessitates the creation of a second wound site (donor site), subjecting the patient to a second severe trauma and additional loss of functionality. Therefore, autografting is utilized only when sufficient autograft tissue is available and when the loss of functionality or morbidity at the primary wound site outweighs that at the harvest site, giving it limited applicability. Typical applications of autografting are following severe burns and peripheral nerve injuries in the hand.

### Permanent Prosthetic Device

Permanent prosthetic devices are typically fabricated from biologically inert materials, such as metals, ceramics, and synthetic polymers, that do not provoke the immune response problems inherent to many transplanted tissues. Even though these devices are fabricated from bio-inert materials, interactions between the prosthesis and the surrounding biological environment still lead to a number of unfavorable physical and biological manifestations. Specific examples are the formation of a thick, fibrous scar tissue capsule around the implant (Rudolph *et al.*, 1992), stress-shielding of the surrounding tissue (Spector *et al.*, 1993), platelet aggregation to implanted surfaces (Snyder *et al.*, 2002), and accumulation of wear particles both at the site of implantation and in the lymphatic system (Urban *et al.*, 2000). The spontaneous remodeling process of the tissues surrounding the implant can also be significantly altered, leading to further tissue degradation (Yannas, 2001). These often-serious side effects illustrate the difficulty of replacing bioactive tissues with bio-inert implants fabricated from materials possessing drastically different material and mechanical properties.

### Stem Cells

The pluripotent nature of stem cells offers a multitude of therapeutic possibilities (Kondo *et al.*, 2003; Lerou and Daley, 2005). Current efforts in stem cell research have focused on understanding stem cell plasticity and ways of controlling stem cell differentiation (Wagers and Weissman, 2004). Previously, mesenchymal (Pittenger *et al.*, 1999), epi-

thelial (Slack, 2000), and neural stem cells (Gage, 2000) have been grown *in vitro* and studied. More recently, experimental investigations of stem cells have also focused on utilizing hematopoietic and embryonic stem cells. In particular, techniques to harvest and identify them (Surdez *et al.*, 2005), expand and differentiate them in culture (Daley, 2005; Lengerke and Daley, 2005; Passegue *et al.*, 2005; Udani *et al.*, 2005; Wang *et al.*, 2005), and reimplant them at an injury site (Kunisaki *et al.*, 2006; Udani *et al.*, 2005) have been at the forefront of stem cell research. While few significant advances have been made to this point, stem cell technologies present a great deal of promise. However, improved understanding of stem cell behavior and development of stem cell-based technologies also raise a number of important ethical questions (Daley *et al.*, 2005), consideration of which will play a significant role in the development of stem cell-based tissue-engineering solutions.

### In Vitro Synthesis

*In vitro* synthesis requires the growth of a functional volume of tissue *in vitro*. *In vitro* synthesis allows for total control over the culture environment, such as soluble regulator content (i.e., growth factors, cytokines), insoluble regulator content (i.e., ECM proteins), and a variety of cell culture media and loading conditions. In order to develop large (critical dimension >1 cm), bioactive scaffolds, it is important to support the cells metabolically within these constructs. There are two mechanisms available for transport of metabolites to and waste products from cells in a scaffold: diffusion and, with *in vivo* applications, transport through capillary networks formed in the scaffold via angiogenesis. While angiogenesis becomes the limiting factor *in vivo*, significant angiogenesis is not observed for the first few days after implantation, and it is not present at all *in vitro*. As a result, current tissue-engineering constructs are size limited (<1 cm) due to diffusion constraints. Improving metabolite influx is critical for larger, more complex scaffolds. Additionally, the complexity of biological systems, specifically cytokine, growth factor, and intercellular signaling needs, throughout the volume of developing tissue has to date precluded, with few exceptions (such as *in vitro* culture of replacement heart valves (Rabkin-Aikawa *et al.*, 2005) and epithelial sheets for severe burn patients (Woodley *et al.*, 1988)), the formation of complex tissues *in vitro*.

### Induced In Vivo Organ Synthesis (Induced Regeneration)

Induced organ synthesis *in vivo* relies on the processes inherently active in the wound site to regenerate lost or damaged tissue. A highly porous analog of the ECM, also termed a *scaffold*, is utilized to induce regeneration at a wound site where the organism would normally respond via repair processes. Induced organ synthesis was made possible by the development of fabrication techniques to produce ECM analogs with well-defined pore microstruc-

ture, specific surface area, chemical composition, and degradation rate (Yannas, 2001; Yannas *et al.*, 1989). Its first application was the use of a collagen–glycosaminoglycan (CG) scaffold (termed *dermal regeneration template* — DRT) that induced skin regeneration following severe injury. The DRT displayed high biological activity when implanted into a full-thickness skin wound and was capable of inducing regeneration of the underlying dermal layer of skin as well as the epidermal and basement membrane layers (Yannas, 2001; Yannas *et al.*, 1989).

For the remainder of this review, we focus on studies of the structure and function of ECM analogs used in tissue-engineering applications as well as an in-depth discussion of the tissue-engineering approaches utilized to induce regeneration of a number of tissues, namely skin, peripheral nerves, and orthopedic tissues.

## IV. ACTIVE EXTRACELLULAR MATRIX ANALOGS

### Fundamental Design Principles for Tissue Regeneration Scaffolds

Porous, three-dimensional scaffolds have been used extensively as biomaterials in the field of tissue engineering for *in vitro* study of cell–scaffold interactions and tissue synthesis and *in vivo* induced tissue regeneration studies. These scaffolds, analogs of the ECM, act as a physical support and, more importantly, as an insoluble regulator of biological activity that affects cell processes such as migration, contraction, and division. For the remainder of this review, the term *active* or *bioactive ECM analog* will refer to scaffolds that induce regeneration of normally nonregenerative tissues following severe injury. It has been hypothesized that these active ECM analogs induce regeneration by establishing an environment that selectively inhibits wound contraction by preventing the organized contractile response and blocking scar synthesis, the two processes normally responsible for closing a wound following severe injury (Yannas, 2001).

Four physical and structural properties must be controlled to critical levels for the fabrication of an active ECM analog: the degradation rate, which defines the template residence time, the chemical composition, the pore microstructure (mean pore size, shape, and orientation), and the scale of the scaffold, which is defined by the critical cell path length (Yannas, 2001). These characteristics and any governing models that help to describe cell behavior in active ECM analogs are discussed briefly in the following sections.

#### Template Residence Time

The length of time the scaffold remains insoluble in the wound site (*residence time*) is critical in defining its bioactivity. For physiologic tissue to be synthesized at a wound site, the scaffold must initially support cell migration, prolifera-

tion, and organization, but the scaffold must then degrade in such a manner that it does not interfere with the native tissue synthesis and remodeling processes. These considerations require a scaffold residence time with an upper and lower bound, a concept that has been formalized as the isomorphous tissue replacement model: scaffold residence time must be approximately equal to the time required to synthesize a mature tissue via regeneration at the specific tissue site under study (Yannas, 2005). In the case of a full-thickness skin wound, for example, this healing time is approximately 25 days, and the degradation kinetics of the active ECM analog that induces skin regeneration was optimized for that time period (Yannas *et al.*, 1989). Alternatively, the healing time of a peripheral nerve injury is dependent on the gap length: Peripheral nerve trunks grow unidirectionally, from the proximal toward the distal stump, at a rate of approximately 1 mm/day (Williams *et al.*, 1983). Accordingly, during induced regeneration of peripheral nerves across a gap, a scaffold in contact with the nerve stumps (either the tube into which the stumps are inserted or the scaffold structure in the tube lumen) must remain in an insoluble state over a period approximately equal to the time, of order 10–20 days, during which axon elongation proceeds from the proximal to the distal stump.

An intact scaffold cannot diffuse away from the wound bed. Therefore the simplest method for achieving isomorphous tissue replacement requires the insoluble scaffold structure to be degraded by enzymes in the wound bed into low-molecular-weight fragments. The lifetime of the scaffold is defined by the degradation time constant ( $t_d$ ) and can be compared to the normal healing-process time constant for a wound at the anatomic site of interest ( $t_h$ ) (Yannas, 2001). When the scaffold remained in the wound bed as a nondegradable implant ( $t_d/t_h > 1$ ), dense fibrous tissue similar to scar was synthesized underneath the scaffold (Yannas, 2001; Yannas *et al.*, 1989). When the scaffold degraded rapidly ( $t_d/t_h < 1$ ), wound healing was marked by wound contraction and scar synthesis, similar to the reparative healing process observed in an ungrafted wound, and no regeneration was observed (Yannas, 2001). Because different wound sites and even the same wound site in different species may have different time constants for healing ( $t_h$ ), it is necessary to adjust the degradation rate of the ECM analog for each wound site and species in order to satisfy the isomorphous tissue replacement requirement and to induce regeneration.

Scaffold resistance to degradation can be increased by increasing the relative density (solid content) of the scaffold. However, a more elegant option that does not involve changing the structural characteristics of the scaffold is also available: Scaffold degradation resistance increases with increasing cross-link density between the fibers that make up the scaffold structure (Harley *et al.*, 2004; Yannas *et al.*, 1975, 1989). In the case of collagen-based scaffolds, degradation in the wound bed is accomplished primarily by native

collagenases. Decreased degradation rates for collagen-based scaffolds have been achieved by introducing glycosaminoglycans (GAGs) into the collagen mixture, which results in the formation of additional cross-links, and by further cross-linking the resultant scaffold using a multitude of physical and chemical cross-linking processes. Dehydrothermal (DHT) cross-linking is a physical technique where the scaffold is exposed to a high temperature under vacuum, leading to the removal of water from the scaffold. Drastic dehydration (<1% water content) of the scaffold leads to the formation of interchain amide bonds through condensation (Yannas and Tobolsky, 1967). DHT cross-linking is adjustable; exposure to higher temperatures or longer lengths of time produces a higher cross-link density and a slower degradation rate (Harley *et al.*, 2004; Yannas, 2001; Yannas *et al.*, 1989). UV treatment is a second physical cross-linking technique that can create cross-links between collagen fibers due to the effects of radiation (J. E. Lee *et al.*, 2001). Chemical cross-linking treatments, such as glutaraldehyde or carbodiimide (J. E. Lee *et al.*, 2001) exposure can also be utilized to induce covalent bonds between collagen fibers. These cross-linking techniques are considerably more powerful, resulting in significantly higher cross-link densities and slower degradation rates. However, chemically cross-linked scaffolds must be extensively washed to remove all traces of the typically cytotoxic chemicals. Additionally, some chemical cross-linkers integrate a portion of the chemical compound into the cross-link. Degradation of these scaffolds releases cytotoxic agents into the wound site, so these techniques must be used with care (J. E. Lee *et al.*, 2001; Olde Damink *et al.*, 1996). While described in detail for collagen-based scaffolds, these cross-linking tools and techniques can be applied to a multitude of scaffolds, fabricated from both natural and synthetic materials.

### Chemical Composition

The chemical composition defines the ligands displayed on the scaffold surface. Cell behaviors such as attachment, migration, proliferation, and contraction are all mediated by interactions between the focal adhesions and integrins expressed on the cell surface and the ligands available on the scaffold surface. An active ECM analog must be fabricated in a manner, and from specific materials, that leads to expression of a chemical environment conducive to cell–scaffold interactions that prevent organized wound contraction and scar synthesis and that instead induce regeneration.

A multitude of different materials has been used to fabricate scaffolds for many tissue-engineering applications, including studies of induced *in vivo* regeneration. Several synthetic, nondegradable polymers such as (poly)dimethyl siloxane have occasionally been utilized. These polymers, which parenthetically violate the principle of isomorphous tissue replacement, do not express ligands on their surface

and have not induced regeneration. Degradable synthetic polymers, such as poly(L-lactide) and poly(lactide-co-glycolide) variants, have been fabricated to satisfy isomorphous tissue replacement and with surfaces that have been modified chemically to display appropriate ligands. However, these materials have not been observed to prevent contraction and scar formation or to induce regeneration of stromal tissue. A chemical composition that has been used successfully to induce regeneration is a graft copolymer of type I collagen and a sulfated glycosaminoglycan (GAG) (Yannas, 2001; Yannas *et al.*, 1989). Collagen is a significant constituent of the natural ECM, and collagen-based scaffolds have been used in a variety of applications due to many useful properties: low antigenic response and a high density of ligands that interact specifically with integrin receptors in fibroblasts (the cell type predominantly responsible for cell-mediated contractions processes during repair). Particular collagen scaffolds have been observed to promote cell and tissue attachment and growth as well as to induce regeneration of tissue following injury (O'Brien *et al.*, 2005; van Tienen *et al.*, 2002; Yannas, 2001; Yannas *et al.*, 1989). However, in order to induce regeneration, the periodic banding (~64 nm) of the collagen fiber structure must be selectively abolished to prevent platelet aggregation that leads to repair (Yannas, 2001). A number of other natural protein-based scaffolds (i.e., hyaluronate-based, fibrin-based, and chitosan-based scaffolds) have also shown great promise in the field of tissue engineering. These natural polymers are also capable of facilitating cell binding similar to that observed with collagen scaffolds, in part due to their expression of natural ligand-binding sites, but at this point these materials have not been developed to the point of inducing regeneration.

### Template Pore Microstructure

The biological activity of any ECM analog also depends significantly on its three-dimensional pore microstructure. Having migrated into the scaffold, the cell interacts with the surrounding scaffold environment, making use of its cell surface receptors to bind to specific ligands on the scaffold surface. The first critical component of ECM analog microstructure to consider is the open- or closed-cell nature of the scaffold. An *open-cell* pore microstructure exhibits pore interconnectivity, whereas a *closed-cell* microstructure exhibits membranelike faces between adjacent pores, effectively sealing the environment of one pore from its neighbors. Pore interconnectivity is critical for scaffold bioactivity in order for cells to be able to migrate through the construct and to interact with other cells in a manner similar to that observed *in vivo*. A second critical structural feature is the relative density ( $R_d$ ) or porosity of the ECM analog. The *relative density* of the scaffold is calculated as the ratio of the scaffold density to the density of the solid from which the scaffold is made. *Porosity*, a measure of how porous the scaffold is, is the pore volume fraction of the scaffold. Addition-

ally, the relative density and porosity are inversely related: Scaffold porosity can also be defined as  $(1 - R_d)$ . Both of these variables define the amount of solid material in the scaffold. When the pores are closed or too small or when the relative density is too large, cells are not able to migrate through the scaffold, a significant impediment for a tissue-engineering scaffold. An active ECM analog must possess an open-cell pore structure with a relative density below a critical value that is characteristic of each application but typically significantly less than 10% (bioactive porosity typically greater than 90%). This structural criteria, determined from the results of a number of experiments studying cell-scaffold interactions, suggest that a critical number of cells are required within a bioactive scaffold (Yannas, 2001).

The mean pore size of the ECM analog significantly influences its bioactivity. The effect of mean pore size will now be discussed in conjunction with the application of cellular solids modeling and a discussion of scaffold specific surface area. To describe even a simple cell-scaffold interaction, a highly detailed model describing the number of receptors utilized per bound cell and the nature of the binding and receptor sites needs to be developed. However, a more generic explanation can be used to describe the complexity of the cell-scaffold interaction and the significant influence the pore size has on its bioactivity. At first pass, it is apparent that there is a minimum pore size requirement for a bioactive ECM analog: The pores must be large enough to allow cells to fit through the pore structure and populate the analog. There is also an observed upper bound to pore size (Yannas, 2001; Yannas *et al.*, 1989). It has been hypothesized that this upper bound in mean pore size is due to the effects of scaffold-specific surface area. To further test this hypothesis, cellular solids modeling techniques have been integrated to better describe scaffold microstructure using a quantitative framework. The complex geometry of foams (and of scaffolds) is difficult to model exactly; instead, dimensional arguments that rely on modeling the mechanisms of deformation and failure in the foam, but not the exact cell geometry, are used (Gibson and Ashby, 1997). Scaffold relative density ( $R_d$ ) and mean pore size ( $d$ ) together define the scaffold specific surface area ( $SA/V$ ), the total surface area of pore walls available for cell attachment. A cellular solids model [Eq. (16.1)] has been developed and experimentally validated to accurately predict  $SA/V$  of collagen-based scaffolds (O'Brien *et al.*, 2005):

$$\frac{SA}{V} = \frac{10.17}{d} (R_d)^{1/2} \quad (16.1)$$

Increasing mean pore size in a series of constructs and keeping  $R_d$  constant decreases the overall  $SA/V$  while increasing  $R_d$ , and keeping the mean pore size constant increases  $SA/V$ . The primary feature of this structural analysis to consider is that a change in the construct  $SA/V$  indicates a change in the available area to which cells bind. This

calculation and experimental result suggests the significance of the scaffold  $SA/V$  in defining its bioactivity. If the  $SA/V$  is too small (i.e., due to a relatively large mean pore size), an insufficient number of cells will be able to bind to the scaffold and the cells that remain free will contribute to the spontaneous repair mechanism.

As previously discussed, there is also a minimum mean pore size, defined by the characteristic dimension of the cell: approximately 10–50  $\mu\text{m}$  for most cells. When the scaffold pore size is smaller than this critical dimension, cells will be unable to migrate through the scaffold; whereas when the pore size is too large, an insufficient specific surface area will be available. These upper and lower bounds of the scaffold mean pore size, mediated by cell size and specific surface requirements, have been determined experimentally for each cell type for tissues where regenerative templates have been used (Yannas, 2001).

The shape of the pores that make up the porous scaffold must also be considered. Cells have been observed to be exquisitely sensitive to the mechanical properties of the underlying substrate (Lo *et al.*, 2000), and slight changes in the mean shape of the pores can result in significant variations in the extracellular mechanical properties (Gibson and Ashby, 1997) and overall construct bioactivity (Chang and Yannas, 1992). Changes in mean pore shape may also play a role in defining the areas of the scaffold available or unavailable for binding and the predominant direction of cell migration as well as in the geometrical organization of cells within the scaffold.

### Critical Cell Path Length

Successful migration of cells into an active ECM analog and their initial survival is critically important for successful regeneration. While the effect of the structural characteristics (i.e., pore size, shape, relative density) on the bioactivity of an ECM analog has been discussed, there is another important characteristic to consider: an adequate source of metabolites (i.e., oxygen, nutrients). There are two mechanisms available for transport of metabolites to and waste products from the cells: diffusion to and from the surrounding wound bed or transport along capillaries that have sprouted into the scaffold as a result of angiogenesis. While angiogenesis becomes the limiting factor for long-term cell survival and growth, significant angiogenesis is not observed for the first few days after implantation. Therefore, early cell survival inside the scaffold is defined solely by diffusion. The critical scaffold thickness, the maximum scaffold thickness than can be supported by metabolite diffusion, has been observed empirically to be on the order of a few millimeters (Yannas, 2001).

A quantitative model of cell metabolic requirements and nutrient diffusion characteristics that defines the critical cell path length for cell migration into a scaffold has been developed to describe the salient features of this process (Harley *et al.*, 2006; Yannas, 2000, 2001). Here, the

complexity of the nutritional requirements of the cell is simplified by generically considering a critical nutrient that is required for normal cell function; such a nutrient is assumed to be metabolized by the cell at a rate  $R$  in moles/mm<sup>3</sup>/s. The nutrient is pictured being transported from the wound bed, where the concentration of nutrient is assumed to be a constant,  $C_0$ , over a distance  $L$  via the exudate until it reaches the cell within the scaffold. Immediately following implantation of the scaffold, nutrient transport is performed exclusively via diffusion that can be modeled using the scaffold diffusivity  $D$  in mm<sup>2</sup>/sec. Dimensional analysis [Eq. (16.2)] readily yields the cell lifeline number ( $S$ ):

$$S = RL^2/DC_0 \quad (16.2)$$

The cell lifeline number characterizes the relative ratio of the rate of nutrient supply to nutrient consumption by the cell. If the rate of consumption of the critical nutrient exceeds greatly the rate of supply,  $S \gg 1$ , the cell will soon die. At steady state ( $S = 1$ ), the rate of consumption of nutrient by the cell equals the rate of transport via diffusion over a distance  $L$ ; at steady state, the value of  $L$  is the critical cell path length,  $L_c$ , the longest distance away from the wound bed that the cell can migrate without requiring nutrient in excess of that supplied by diffusion. For many cell nutrients of low molecular weight  $L_c$  is of the order of a few hundred micrometers to a few millimeters, a distance short enough to suggest the need for very close proximity between wound bed and implant and to indicate that *in vivo* regeneration of large tissue or organs requires incorporation of special promoters to angiogenesis (Yannas, 2001).

As a result, recent experimental work has focused on understanding the relationship between scaffold pore microstructure and permeability. Scaffold permeability controls diffusion-based metabolite and waste transport to and from the scaffold and influences the final hydrostatic pressure distribution in the scaffold. Both of these parameters can significantly influence cell behavior and overall scaffold bioactivity. Cellular solids modeling tools that quantitatively describe scaffold permeability in terms of salient microstructural features have been utilized in this analysis. Both scaffold pore size and compressive strain can vary significantly with different applications, making them the primary features to characterize in terms of scaffold permeability. An open-cell foam, cellular solids model has been developed to accurately model scaffold permeability ( $K$ ) in terms of scaffold mean pore size ( $d$ ), percent compression ( $\epsilon$ ), a system constant ( $A$ ), and scaffold relative density ( $\rho^*/\rho_s$ ) (Harley *et al.*, 2006) (O'Brien, F. J., Harley, B. A., Waller, M. A., Yannas, I. V., Gibson, L. J., and Prendergast, P. J., 2007):

$$K = A \cdot d^2 \cdot (1 - \epsilon)^2 \cdot \left(1 - \frac{\rho^*}{\rho_s}\right)^{3/2} \quad (16.3)$$

The cellular solids model [Eq. (16.3)] of scaffold permeability suggests that scaffold permeability increases with

**FIG. 16.2.** Bioactivity of ECM analog variants for skin regeneration versus scaffold mean pore diameter (Yannas *et al.*, 1989).

increasing pore size and decreases with increasing compressive strain, a result that has also been observed experimentally for a series of collagen-based scaffolds. The excellent comparison between experimentally measured permeability and what is predicted from the cellular solids model suggests that such predictive modeling tools can be used to describe scaffold permeability for many different scaffold architectures under a variety of physiological loading conditions.

### Active Collagen-Glycosaminoglycan Scaffolds

Collagen-glycosaminoglycan scaffolds have been observed to have a high degree of bioactivity and to be able to induce regeneration of nonregenerative tissues at a variety of anatomical sites. Three specific wounds and the appropriate ECM analogs have been studied in our laboratory: skin regenerated via the dermal regeneration template (DRT) (Yannas, 2001; Yannas *et al.*, 1989), peripheral nerves regenerated by the nerve regeneration template (NRT) (Chamberlain *et al.*, 1998; Chang and Yannas, 1992; Harley *et al.*, 2004), and the conjunctiva regenerated by a modified DRT (Hsu *et al.*, 2000). As predicted, the bioactivity of the DRT and NRT has been found to be closely related to specific physical parameters of the scaffold. Scaffold mean pore size (Fig. 16.2) (Yannas *et al.*, 1989), degradation rate (Figs. 16.3 and 16.4) (Harley *et al.*, 2004; Yannas *et al.*, 1989), chemical composition (Yannas *et al.*, 1989), pore orientation

**FIG. 16.3.** Bioactivity of ECM analog variants for skin regeneration versus scaffold degradation rate (Yannas *et al.*, 1989).

(Chang and Yannas, 1992), and the pore volume fraction have all been shown to have a significant effect on the quality of regeneration, and it appears that only a narrow range of structural features satisfies the criteria for bioactivity (Yannas, 2001).

## V. BASIC PARAMETERS FOR *IN VIVO* REGENERATION STUDIES: REPRODUCIBLE, NONREGENERATIVE WOUNDS

*In vivo* regeneration of injured or excised tissue can be modeled as a process taking place within a bioreactor surrounded by a reservoir with constant properties; the bioreactor symbolizes the entire organism with its complex homeostatic mechanisms. From an engineering standpoint, the bioreactor must have a defined and consistent anatomical and physicochemical environment for quantitative study of any biological process. In order to study induced *in vivo* regeneration, it is therefore critical to standardize the wound site where studies are performed. Without a standardized,

**FIG. 16.4.** Histomorphometric, cross-sectional images of the regenerated nerve trunk from the five collagen tubes with distinct degradation rates, devices A to E. The devices are arranged in order of lowest to highest cross-link density, or most rapid to slowest degradation rate, from A to E. Nerve trunks regenerated in devices C and D, characterized by intermediate levels of the cross-link density and degradation rate (device half-life: 2–3 weeks), showed superior morphology, with significantly larger axons, a more well-defined myelin sheath, and a significantly larger N-ratio. Light-micrograph images of toluidine blue-stained cross sections of regenerated axons taken from the midpoint of the 15-mm gap. Scale bar = 25  $\mu$ m (Harley *et al.*, 2004).

reproducible wound site, it is impossible to assess differences accurately and statistically between ECM analogs within a single laboratory or to compare results from different, independent laboratories. Billingham and Medawar (1955) introduced the concept of an anatomically constant wound for the study of massive skin injuries. This concept has been amplified and standardized. It is referred to as the *anatomically well-defined wound* (Yannas, 2001) and has been applied to the study of injuries in skin, peripheral nerves, and a variety of other wound sites. The anatomically well-defined wound for studies of skin regeneration is the full-thickness skin wound where all tissue (epithelia, basement membrane, stroma) is removed down to the underlying fascia (Yannas, 2001). For peripheral nerve regeneration studies, the standardized wound is complete transection (total or full axotomy) of the nerve trunk, typically at the midpoint of the sciatic nerve (Yannas, 2001). For studies of cartilage repair following injury, the standardized wound model is complete removal of the cartilage down to the underlying subchondral bone (Capito and Spector, 2003). These models standardize the experimental wound environment, making it possible to obtain statistically significant results that can be compared meaningfully. However, in clinical cases, the nature of the wounds typically varies on a case-by-case basis, and it is important to understand the applicability of each treatment methodology to the range of injuries encountered. For example, while a tubular scaffold can be used to study peripheral nerve regeneration using the full axotomy model, a tubular implant would be difficult to implement clinically in the case of severe crush injuries that do not result in complete nerve trunk transection.

## VI. EXAMPLES OF IN VIVO ORGAN REGENERATION

### Skin Regeneration

Patients exhibiting skin wounds with loss of a substantial fraction of total body surface area (TBSA) face an immediate threat to their survival, originating primarily from the loss of their epidermis. One result of this loss is an increase by an order of magnitude of the moisture evaporation rate, which, if left uncorrected, leads to excessive dehydration and shock. Another result is a sharp increase in risk for massive bacterial infection, which, if allowed to progress, frequently resists treatment and leads to sepsis. Even when patients manage to survive these immediate threats, there is a residual serious problem of quality of life, originating in the occurrence of crippling contractures and disfiguring scars due to the physiological repair process. Conventional treatment is based on use of autografting, which yields excellent results at the treatment site but is burdened by the trauma caused at the donor site as well as by the unavailability of donor sites when the TBSA exceeds about 40–50%.

Of the three major tissue types that together comprise skin, the epidermis and basement membrane layers regenerate spontaneously following injury, provided there is a dermal substrate (stromal layer) underneath. Complete regeneration of the damaged epithelia and basement membrane is typically observed following first- and second-degree burns, small cuts and scrapes, and blisters. However, complete skin regeneration is not observed in the case where substantial damage to the underlying stroma occurs. Such cases include third-degree burns, deep cuts, and scrapes. In these cases, similar to the full-thickness, anatomically well-defined wounds created for studies of skin regeneration, organized wound contraction and scar synthesis is observed. A more in-depth description of the skin tissue triad, salient anatomical features, and its regenerative capacity has been previously published (Yannas, 2001).

In addition to the clinical success of the collagen-based dermal regeneration template (DRT), four other technologies developed to induce skin regeneration have achieved variable levels of success and are briefly discussed here to motivate further thought about scaffold-based options for treating severe injuries. In the following sections, the DRT, cultured epithelial autograft (CEA), living dermal replacement (LDR), living skin equivalent (LSE), and the naturally derived collagen matrix (NDCM, Alloderm) are discussed.

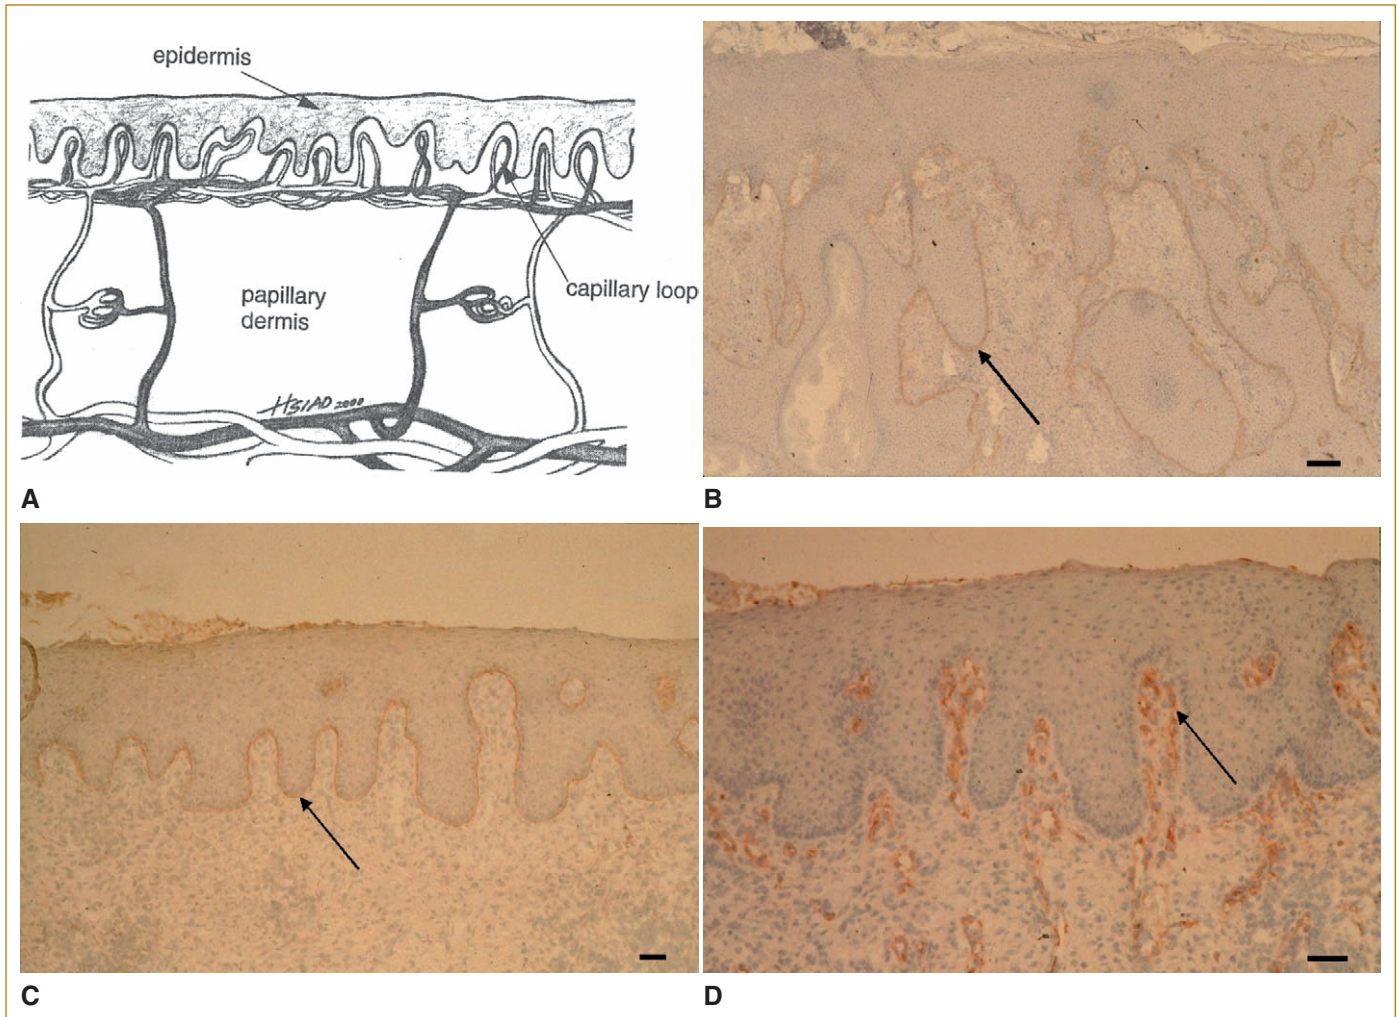

### Dermal Regeneration Template (DRT)

The dermal regeneration template (DRT) is a collagen–glycosaminoglycan scaffold whose microstructural and materials properties have been optimized to produce a bioactive ECM analog that, when implanted, induces sequential regeneration of the underlying dermis and resultant regeneration of the basement membrane and epithelial layers. The effectiveness of the DRT has been demonstrated clinically with a population of massively burned patients (Yannas, 2001) and in animal experiments utilizing a full-thickness (anatomically well-defined skin wound) skin wound (Yannas, 2001; Yannas *et al.*, 1989).

The DRT is typically used as an acellular implant that induces regeneration of the dermis, thereby providing the essential substrate for spontaneous regeneration of the epidermis and basement membrane layers. Following dermal regeneration by the unseeded DRT, epidermal cells from the wound edges migrate into the center of the wound and form a mature epidermis and basement membrane in a process termed *sequential regeneration* (Yannas, 2001). The resultant regeneration of appropriate tissue layers (tissue triad), along with associated structures (i.e., rete ridges), has indicated that the DRT is capable of inducing regeneration of mature skin in a full-thickness skin wound model (Fig. 16.5) (Compton *et al.*, 1998).

Clinically, the DRT is used as an acellular, bilayer device consisting of an inner layer of the active ECM analog and an outer layer of elastomeric poly(dimethyl siloxane). The layer of silicone is removed about two weeks after grafting the

**FIG. 16.5.** (A) Diagram of normal skin showing the characteristic rete ridges at the dermo–epidermal junction and the vascular network (capillary loops) that populates the subepidermal region (Yannas, 2001). (B) As early as 12 days after grafting a full-thickness skin wound with a keratinocyte-seeded DRT, anchoring fibrils were observed in the regenerating basement membrane (arrow). The basal surface epithelium and the periphery of the epithelial cords are labeled with type VII collagen immunostaining, identifying the anchorage structures at the dermo–epidermal interface. Bar: 150  $\mu\text{m}$ . (C) As early as 35 days after grafting a full-thickness skin wound with a keratinocyte-seeded DRT, a confluent hemidesmosomal staining pattern is observed at the dermo–epidermal junction (arrow) by immunostaining for the  $\alpha_6\beta_4$  integrin. The pattern observed in the regenerating skin is identical to that observed in physiologic skin. Bar: 100  $\mu\text{m}$ . (D) A full-thickness skin wound grafted with a keratinocyte-seeded DRT was observed to regenerate many of the structures observed in normal skin. Immunostaining for factor VIII 35 days after grafting revealed that capillary loops had formed in the rete ridges of the regenerated dermis (arrow), similar to those observed in physiologic skin. Bar: 75  $\mu\text{m}$  (Compton *et al.*, 1998).

device, having served the important temporary role of controlling moisture flux and bacterial invasion at the site of organ synthesis. The DRT is fabricated from collagen–glycosaminoglycan copolymer, with a 98 : 2 ratio of microfibrillar, type I collagen to chondroitin 6-sulfate. The microstructure of the DRT has been optimized with both a lower and an upper pore size bound of  $20 \pm 4 \mu\text{m}$  and  $125 \pm 35 \mu\text{m}$ , respectively. Additionally, the biodegradation rate of the DRT has been optimized with lower and upper bounds of residence time in the wound bed of 5 and 15 days, respectively (Yannas, 2001; Yannas *et al.*, 1989). Clinical use of the DRT has emphasized treatment of patients with massive

burns as well as those who require resurfacing of large or small scars from burns. The DRT is responsible for regenerating the underlying dermal architecture, providing the appropriate stromal layer on which native regenerative processes of the basement membrane and epithelial layer can take place. For wounds of relatively small characteristic dimension, e.g., 1 cm, epithelial cells migrating at speeds on the order of 0.5 mm/day from the wound edges can provide a confluent epidermis within 10 days. In such cases, the unseeded DRT fulfills all the design specifications set for successful *in vivo* skin regeneration. However, the wounds incurred by a massively burned patient are typically of char-

acteristic dimension of several centimeters, often more than 20–30 cm. These wounds are large enough to preclude formation of a new epidermis by cell migration alone within a clinically acceptable time frame. Current clinical protocol favors harvesting and use of a very thin autoepidermal graft from another part of the patient's body, thin enough not to leave behind a scarred donor site, to cover the neodermis (Yannas, 2001), or application of a cultured epithelial autograft (described later) on top of the DRT following removal of the poly(dimethyl siloxane) membrane.

A keratinocyte-seeded DRT has been used in guinea pig and swine animal models. The keratinocyte-seeded DRT induces simultaneous formation of a dermis as well as the epidermal and basement membrane layers and removes the requirement for epithelial cell-mediated migration from the wound edges for successful skin regeneration. Although the keratinocyte-seeded DRT induces *simultaneous regeneration* of skin in the guinea pig model, an animal model characterized by extensive organized wound contraction that is significantly more severe than that observed with humans, the sum total of the results of studies using the DRT suggest that *in vivo* synthesis of skin in the clinical setting does not require anything more than the DRT (Yannas, 2001).

### Cultured Epithelial Autograft (CEA)

Cultured epithelial autografts (CEAs) are an epidermal graft formed from a sheet of keratinocytes grown *in vitro* and then implanted into the wound site. A small epidermal sample is removed from the patient and dissociated, and the resultant cells are then cultured *in vitro* until they form an epithelial membrane. However, in the case of full-thickness skin wounds where there is no underlying dermis to support the epidermal sheet, rapid CEA degradation is typically observed and long-term clinical applicability has not been observed. In particular, one persistent problem is the formation of blisters under large areas of the graft (avulsion). However, in the case of partial-thickness wounds where a significant portion of the stroma remains, the “take” of the CEA graft has been very good. As such, the CEA has been used to cover significant areas, as large as 50% of the TBSA, for partial-thickness wounds and as a temporary solution for full-thickness wounds to prevent immediate wound dehydration and infection, making the CEA a life-saving, although temporary, graft (Yannas, 2001). Additionally, regardless of whether the graft was placed on a partial- or full-thickness skin wound, the resulting CEA graft exhibited mechanical fragility due to a lack of the 7-S domain of type IV collagen, anchoring fibrils, and rete ridges (Woodley *et al.*, 1988). These structures, required for the formation of a physiological dermo-epidermal junction as well as for the formation of a physiological collagen and elastin fiber architecture observed in the normal, adult dermis, are not formed after grafting of the wound site with the CEA (Yannas, 2001). Without these structures, the CEA cannot be used as a per-

manent skin replacement; instead, the CEA is often used as a temporary coverage as part of a more substantial treatment regimen, such as autografting or DRT implantation.

### Living Dermal Replacement (LDR)

The LDR (living dermal replacement) is a polyglactin-910 nylon surgical mesh scaffold fabricated from a copolymer of 90 wt% glycolic acid and 10 wt% lactic acid termed PGL that was developed to be an analog of the ECM and induce skin regeneration following injury. The PGL fibers, approximately 100  $\mu\text{m}$  in thickness, were knitted into a mesh that exhibits a pore microstructure with a characteristic dimension of 280–400  $\mu\text{m}$ . This mesh structure presented a large-weave structure relative to the characteristic cell dimension of approximately 10  $\mu\text{m}$  that allowed rapid cell incorporation and ample nutrient diffusion. Prior to implantation, the acellular PGL mesh was cultured *in vitro* with fibroblasts until the cells were observed to synthesize several important ECM components, such as collagen and elastin, *in vitro*. Immediately prior to implantation, the upper surface of the PGL scaffold was seeded with keratinocytes to produce a bilayer graft. Once the keratinocytes reached confluence on the surface of the PGL mesh, the entire structure was grafted into the wound site (Hansbrough *et al.*, 1993). A thin, fragile epidermal layer typically developed by 10 days postgrafting and became cornified as early as 20 days postgrafting. Additionally, by 20 days postgrafting the LDR scaffold had degraded completely, with minimal inflammatory response. While the interface between the graft and the wound bed stained positive for laminin, consistent with the synthesis of a lamina lucida layer, no other component of the basement membrane was synthesized. In addition, rete ridges were not synthesized, and a thick layer of fibrotic tissue with a large fibroblast population and vascular ingrowth, characteristic of scar tissue formation, was observed below the newly synthesized epidermal layer. In summary, while the LDR showed the ability to induce regeneration of a neoepidermis, it did not exhibit the ability to induce regeneration of a complete basement membrane or dermal layer (Hansbrough *et al.*, 1993).

### Living-Skin Equivalent (LSE)

The LSE (living-skin equivalent) was formed by populating a collagen lattice with dermal fibroblasts that *in vitro* contracted the lattice and synthesized additional ECM proteins, forming a neo-dermal layer (Bell *et al.*, 1983). Similar to the LDR, after the initial culture period, the upper surface of the neo-dermal layer was seeded with a suspension of keratinocytes. Once seeded, the keratinocytes attached to the collagen construct, proliferated, and differentiated to form a multilayered, epidermal structure within one to two weeks, all *in vitro*. Although short segments of the lamina densa were observed along the dermo-epidermal convergence *in vitro*, the cultured LSE did not exhibit a complete basement membrane layer, rete ridges, or any other skin

appendages at the end of the *in vitro* culture period (Nolte *et al.*, 1994). At this point, the construct was then implanted into the wound site. Continued structural and biological changes were observed in the LSE following grafting, indicating that remodeling was taking place (Yannas, 2001). A functional, fully differentiated epidermis was observed as early as seven days following grafting, and by 14 days a vascularized subepidermal layer with many of the structural characteristics of normal dermis, such as a “basketweave” collagen fiber pattern, was present. However, continued maturation into a formalized dermal region was not observed. Experimental results across multiple animal models and experimental trials were consistent in indicating that the LSE was able to induce regeneration of a mature epidermis and basement membrane, but a mature dermal layer was not observed and the dermo–epidermal junction remained flat, without any sign of rete ridges (Yannas, 2001).

### Naturally Derived Collagen Matrix (NDCM)

Instead of relying on technologies to fabricate a three-dimensional scaffold structure from either synthetic or natural materials (i.e., LSE, LDR, DRT), the naturally derived collagen matrix (NDCM) technology uses decellularized dermal tissue as a scaffold to induce skin regeneration. The NDCM was designed to act as an appropriate ECM analog, because it is the dermal ECM that supports normal tissue remodeling following severe injury, thereby inducing regeneration. The main advantage of the NDCM over a homograft (cellularized dermal tissue from a human donor) and xenograft (cellularized dermal tissue from an animal donor) is that owing to decellularization, the antigenicity of the scaffold is significantly reduced, thereby eliminating the incidence of rejection. The NDCM has been used primarily to treat full-thickness burns and burns to areas of the skin where contraction and scar formation would inhibit functionality (i.e., feet and hands). The NDCM is typically implanted into full-thickness skin wounds and is often covered by a thin autograft of the patient’s own epidermis to speed the healing process. This treatment, similar to that observed with the use of the DRT, results in a high percentage of graft take. Additionally, the thin autograft of epidermal tissue significantly decreases the time for complete graft reepithelialization. Patients showed normal range of motion, grip strength, motor control, and functionality along with formation of appropriate anatomical structures (i.e., rete ridges) following treatment (Tsai *et al.*, 1999), demonstrating the utility of a naturally derived material in tissue-engineering applications.

### Peripheral Nerve Regeneration

The mammalian peripheral nervous system also consists of a distinct tissue triad. Thousands of axons make up a nerve trunk, where each axon is surrounded sequentially by an epithelial, basement membrane, and stromal layer. Schwann cells wrap around the individual axon, forming the

myelin sheath that constitutes the cell-continuous epithelia (Bunge and Bunge, 1983). Surrounding the epithelia is the acellular ECM layer (basement membrane) connecting the myelin sheath and the stromal layer (Fig. 16.1). The endoneurium is the stromal layer of cells, blood vessels, and ECM that surrounds, insulates, and protects all nerve fibers (Yannas, 2001). Similar to that observed with skin, the myelin sheath (epithelia) and basement membrane regenerate spontaneously following injury (Fig. 16.6), while the endoneurium (stromal layer) does not (Chamberlain *et al.*, 1998; Yannas, 2001).

### General Findings

While there have been a large number of studies investigating many different device designs, few have been shown to perform as well as the peripheral nerve autograft (typically the sural nerve from the leg), and none appears to have been able to improve over the autograft for gaps larger than 10 mm (Chamberlain *et al.*, 1998). For studies of peripheral nerve regeneration, complete axotomy (total severance of the nerve trunk) was utilized as the standardized wound model. An analysis of efficacy of the various devices is presented here using the critical axon elongation method (Yannas, 2001) in an attempt to identify optimal device parameters for successful and optimal peripheral nerve regeneration. This method identifies the relative regenerative capacity of different devices by comparing their critical axon elongation, the gap length at which 50% of the implanted devices induce reinnervation between the proximal and distal nerve stumps via elongating axons. Using this technique, increased critical axon elongation length ( $L_c$ ) indicates superior regenerative capacity.

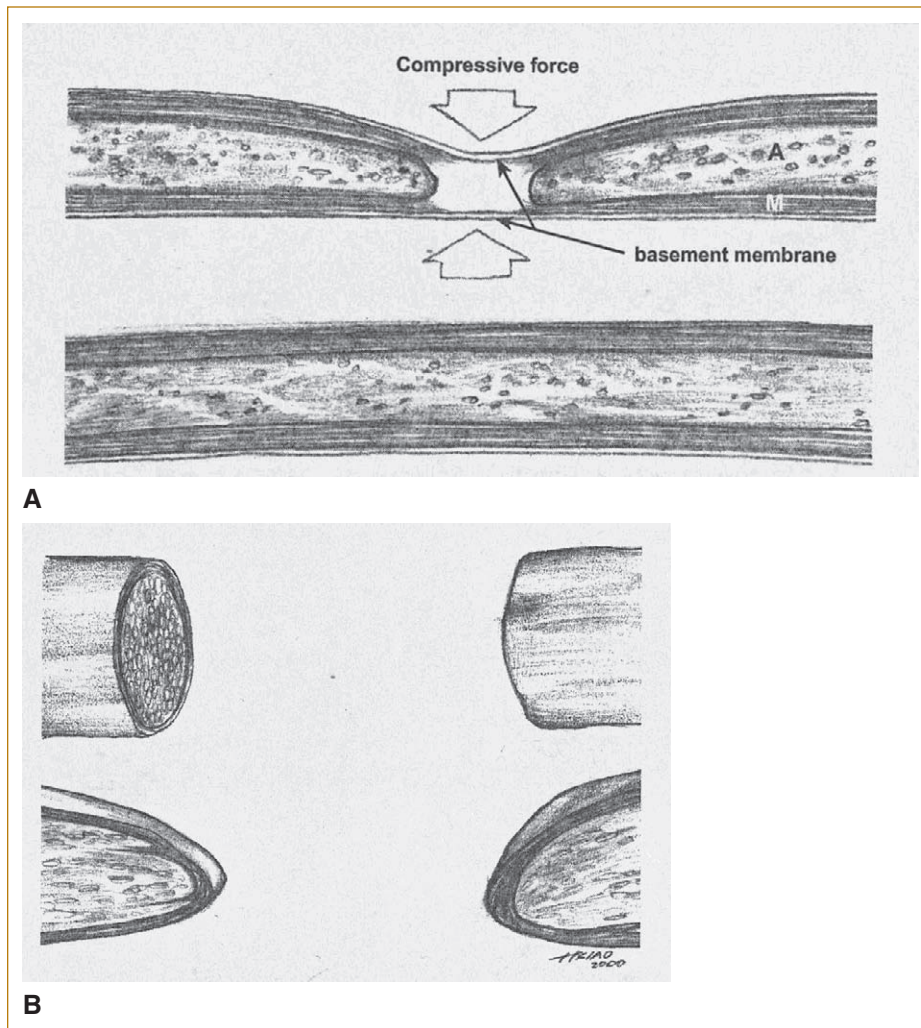

### Effect of Tubulation

Peripheral nerve regeneration is not observed in the absence of a tubular device connecting the two ends of a transected nerve stump if the gap between the two transected stumps is greater than a few millimeters (Yannas, 2001). It has also been observed that insertion of the distal stump into the tube is required for successful regeneration (Chamberlain *et al.*, 1998; Yannas, 2001). This result indicates that even though axon elongation takes place from the proximal to the distal stump, the distal stump appears to provide a critical cytokine field responsible for guiding axon elongation (neurotrophic effect). However, while it has been observed that a tube is all that is required to induce regeneration across a gap of modest length following complete transection, the physical parameters of the tube and any material in the tube lumen significantly affect the kinetics and quality of regeneration; these are discussed in the remaining sections of this chapter.

### Effect of Tube Chemical Composition

A variety of natural and synthetic polymers have been used in peripheral nerve regeneration conduits, and the

**FIG. 16.6.** (A) Axons and myelin sheath inside a nerve fiber are regenerative. Following mild crush injuries, the axoplasm (A) and myelin sheath (M) degenerate along the length of the crushed nerve fiber, but the basement membrane remains intact throughout. Spontaneous regeneration of the nerve fiber occurs within a few weeks of injury. (B) Most of the supporting tissues (stroma) surrounding nerve fibers are not regenerative. Although axons are regenerative following transection, the remainder of the nerve trunk is not. Following transection, each stump is closed via cell-mediated contraction and neuroma synthesis (Yannas, 2001).

choice of tube (conduit) composition has been found to significantly affect the quality of regeneration. For a complete review of the literature, please consult previous publications by the authors (Yannas, 2001; Harley and Yannas, 2006). Early conduits were produced from naturally occurring materials that were easily harvested and implanted, such as bone, dura, perineurium, and blood vessels (Yannas, 2001). More recent devices have utilized nondegradable, synthetic materials, such as stainless steel, rayon, and silicone, as well as degradable, synthetic polymers, such as polyester, polyglactin, and polylactate, and natural polymers, such as collagen, laminin, and fibronectin (Yannas, 2001).

Nondegradable tubes have typically resulted in a poor quality of regeneration marked by significant formation of a neural scar (neuroma) (Chamberlain *et al.*, 1998; Yannas, 2001). Conversely, conduits fabricated from ECM components, specifically collagen, fibronectin, and laminin, have been generally shown to enhance the quality of peripheral nerve regeneration (Bailey *et al.*, 1993; Chamberlain *et al.*, 1998; Ohbayashi *et al.*, 1996; Yannas, 2001). Collagen tubes in particular have been observed to induce the highest

quality of regeneration, as measured by both morphological and electrophysiological methods (Archibald *et al.*, 1995; Chamberlain *et al.*, 1998; Yannas, 2001). It has been hypothesized that this optimal chemical composition was observed because collagen tubes contain inherently bioactive binding sites (ligands) for attachment and migration of various cell types and can be manufactured in such a way that the tube wall pore structure can display a range of cell and protein permeability. Additionally, the degradation rate of the collagen tubes can be tailored to degrade with half-lives that vary over a very wide range to meet the requirements of the isomorphous tissue replacement model (Chang and Yannas, 1992; Harley *et al.*, 2004).

#### Effect of Tube Permeability

Conduit permeability significantly affects the mechanism and quality of peripheral nerve regeneration. *Tube permeability* can be defined by its initial structural features (i.e., scaffold porosity, pore size) or its degradation characteristics (i.e., rapid degradation quickly permeabilizes the tube). Additionally, the conduits may be protein permeable

but cell impermeable or cell and protein permeable. No appreciable increase in the quality of peripheral nerve regeneration was observed for the protein-permeable and cell-impermeable conduit compared to the impermeable conduit (Jenq and Cosseshall, 1987). However, cell- (and therefore protein-) permeable tubes exhibited significantly superior regenerative capacity as compared to impermeable as well as protein-permeable and cell-impermeable conduits (Jenq and Coggeshall, 1987; Jenq *et al.*, 1987; Li *et al.*, 1992; Rodriguez *et al.*, 1999; Yannas, 2001). Device permeability also significantly influences the contractile response following peripheral nerve injury; permeable collagen tubes display a significantly thinner contractile capsule surrounding the regenerating nerve trunk than biodurable silicone tubes (Chamberlain *et al.*, 1998). It is hypothesized that device permeability reduces myofibroblast-mediated contraction of the wound site by permitting migration of the contractile cells away from the wound site through the tube wall (Yannas, 2001) and by allowing connective tissue cells from the surrounding environment access to the tube lumen (Jenq and Coggeshall, 1987).

#### Effect of Tube Degradation Rate

A biodurable conduit, such as a silicone tube, initially induces partial reinnervation between proximal and distal stumps following implantation (Chamberlain *et al.*, 1998). However, as the initially regenerated nerve trunk remodels and matures, the silicone tube constricts this process, resulting in pain and eventual degeneration of the regenerated nerve; prevention of the ultimate degeneration of the initially regenerated nerve trunk requires a difficult second surgical procedure that can further harm the nerve trunk. For this reason, one of the historical goals in studies of peripheral nerve regeneration studies is identification of a suitable degradable conduit. Superior performance of biodegradable tubes compared to tubes made from materials that were either biodurable or which had a very low degradation rate has since been reported in studies by several investigators (Harley *et al.*, 2004; Itoh *et al.*, 2001; Navarro *et al.*, 1996; Rodriguez *et al.*, 1999; Valero-Cabre *et al.*, 2001; Yannas, 2001). Examples include comparison of tubes made of two biodurable polymers, silicone and poly(tetrafluoroethylene), and two degradable polymers, a copolymer of poly(lactic acid) and  $\epsilon$ -caprolactone (PLA/PCL) as well as collagen (Navarro *et al.*, 1996). This study indicated that the degradable tubes induced a higher quality of regeneration as compared to the biodurable tubes over a 6-mm gap in the mouse sciatic nerve. Additionally, a number of degradable collagen tubes have been shown to perform as well as the autograft, considered to be clearly superior to regeneration via a silicone tube and commonly thought to fall short functionally only of physiological (preinjury) nerve (Archibald *et al.*, 1995; Chamberlain *et al.*, 1998; den Dunnen *et al.*, 1996; Molander *et al.*, 1983; Robinson *et al.*, 1991; Yannas, 2001).

While the regenerative advantage of a degradable tube versus a biodurable tube is supported by the evidence, there have not been many extensive studies on the effect of the magnitude of the degradation rate and whether an optimal degradation rate exists, as has been found in the study of ECM analogs (the DRT) to induce skin regeneration (Yannas *et al.*, 1989). Recently, one of the first comprehensive studies of the effect of the degradation rate of collagen tubes on the quality of peripheral nerve regeneration has been published by these authors. This study utilized a 15-mm gap in the rat sciatic nerve and evaluated the regenerative capacity of a homologous series of porous, collagen tubes, showing a significant effect of degradation rate on the quality of peripheral nerve regeneration (Harley *et al.*, 2004). The chemical composition, pore structure, and permeability of the conduits in this study were kept constant, while the cross-link density was steadily increased to create a series of five devices with *in vivo* degradation half-lives varying between <1 week and >100 weeks. The quality of peripheral nerve regeneration was observed to vary significantly with tube degradation rate; the highest quality of peripheral nerve regeneration was observed for tubes with a degradation half-life of two to three weeks (Fig. 16.4) (Harley *et al.*, 2004). These data suggest that the positive effects of tubulation in treating peripheral nerve injuries are due to the presence of the tube immediately following injury; tubulation appears to significantly affect the early mechanisms of peripheral nerve regeneration. A speculative view of the maximum regenerative activity observed in the present study can be based on the putative existence of a lower and higher limit in tube degradation rate, similar to that observed for the dermal regeneration template (Yannas *et al.*, 1989). When the degradation rate of the collagen tubes is excessively slow, the tubes behave as if they were biodurable, remaining intact long enough to interfere with tissue remodeling. In contrast, tubes that degrade very rapidly fail to maintain a protected environment for regeneration, which is the basis for the use of tubulation to promote nerve regeneration.

#### Effect of Tube Filling

A wide variety of solutions, ECM analogs, and cell suspensions have been introduced into the tube lumen in an effort to improve the quality of peripheral nerve regeneration. Use of ECM macromolecules, such as collagen, laminin, and fibronectin, in both solution and gel form, has been observed to have no significant effect on peripheral nerve regeneration. Furthermore, when gel concentrations exceeded certain critical levels, a negative effect on the quality of regeneration is observed (Bailey *et al.*, 1993). However, a laminin-coated collagen-based scaffold has been observed to improve the quality of regeneration, implying the requirement of an insoluble structure within the tube lumen in addition to any soluble regulators to improve the quality of regeneration (Ohbayashi *et al.*, 1996).

Several insoluble substrates, ECM analogs inserted into the empty lumen of the tube prior to implantation, have shown significant regenerative activity. Examples include highly oriented fibrin fibers and axially oriented polyamide filaments that significantly improved the quality of regeneration (Lundborg *et al.*, 1997; Williams *et al.*, 1987). Specific ECM analogs have been observed to significantly increase the maximal gap length that can be bridged by axonal tissue (Madison *et al.*, 1988; Yannas, 2001), the speed of axonal bridging (Madison *et al.*, 1988; Ohbayashi *et al.*, 1996), and the quality of regeneration (Chamberlain *et al.*, 1998; Chang and Yannas, 1992; Yannas, 2001).

The ECM analog that has been found to induce the highest quality of regeneration is a collagen-based scaffold termed the *nerve regeneration template* (NRT) (Chang and Yannas, 1992; Yannas, 2001). The NRT has induced regeneration of a functional peripheral nerve across gaps varying from 10 to 15 mm in the rat sciatic nerve (Chamberlain *et al.*, 1998; Yannas, 2001). Like the DRT, the microstructural and material properties of the NRT have been optimized. The highly bioactive NRT is characterized by axially (extending between the proximal and distal stumps) elongated pore tracks defined by axially oriented ellipsoidal pores with a mean pore size of approximately 35  $\mu\text{m}$  (Chang and Yannas, 1992). This pore structure is hypothesized to improve the quality of peripheral nerve regeneration by providing directional guidance to the formation of linear Schwann cell columns, which act as tracks for axon elongation (microtube hypothesis) (Yannas, 2001; Zhao *et al.*, 1997). The positive effect of an axially oriented fiber structure has also been observed using a fibrin fiber-based ECM analog in the tube lumen (Williams *et al.*, 1987). The degradation rate of the NRT has also been found to significantly affect the quality of regeneration, with an *in vivo* degradation half-life on the order of six weeks found to be optimal; NRT variants that degraded too rapidly or too slowly led to significantly poorer functional recovery (Chang and Yannas, 1992; Yannas, 2001). The long-term morphological structure and electrophysiological function of nerves regenerated using the NRT have been observed to be at the level of an autografted nerve, the current gold standard for peripheral nerve injury treatment (Chamberlain *et al.*, 1998).

Soluble regulators and cell suspensions have also been introduced into the tube lumen in an effort to improve the quality of regeneration. Suspensions of Schwann cells showed very significant regenerative activity (Ansselin *et al.*, 1997), further supporting the microtube hypothesis, which describes nerve regeneration as dependent on early formation of linear columns of Schwann cells extending from the proximal toward the distal nerve trunk. In addition to the use of a cell suspension, solutions of acidic (aFGF) and basic fibroblast growth factor (bFGF) were also observed to improve the quality of regeneration (Walter *et al.*, 1993). However, the use of nerve growth factor (NGF) was not found to improve the quality of regeneration (Hollowell *et al.*, 1990).

A variety of conclusions have been drawn about the relative efficacy of the various biomaterials and devices employed in the study of peripheral nerve regeneration. Nerve chamber configurations that had the highest regenerative activity were those in which the tube wall comprised certain synthetic biodegradable polymers, such as collagen, was cell permeable rather than protein permeable or impermeable, and had an *in vivo* degradative half-life on the order of two to three weeks. Introduction of an insoluble regulator (ECM analog in the form of a scaffold) into the tube lumen, but not of ECM components in a gel or solution form, also significantly improves the quality of regeneration. The optimal ECM structures were found to be highly porous, with controlled degradation rates and an axially aligned micro structure. In addition, suspensions of Schwann cells as well as solutions of either acidic or basic fibroblast growth factor placed within the tube lumen with or without an insoluble ECM analog have been shown to improve the quality of regeneration.

### Cartilage Regeneration

Articular cartilage contains an avascular, non-neural ECM composed primarily of type II collagen and glycosaminoglycans. Compared to other tissues, cartilage possesses a very low cell density and a very high ECM density. The chondrocytes populating the cartilaginous ECM display low proliferative activity and, due to the high ECM protein density, are unable to migrate through the tissue. Due to the low proliferative activity, avascularity, and high ECM protein density, injuries to cartilage display an injury response distinct from traditional injury responses, characterized by inflammatory processes, cell-mediated contraction, and scar synthesis. No repair or regeneration processes are observed *in vivo* following cartilage injuries; instead, the scope of injury increases as the wound edges become increasingly degraded, eventually compromising the joint (Capito and Spector, 2003). Severe cartilage injuries are extremely prevalent in today's active society, resulting in pain, decreased patient activity, and eventually disability, profoundly impacting quality of life. The current methods for treating such focal cartilage defects include microfracture, autologous chondrocyte implantation, and osteochondral autografting (Capito and Spector, 2003). In the case of microfracture and autologous chondrocyte implantation, a flap of periosteum is sewn over the cartilage defect area and is sealed with fibrin glue. With microfracture, immediately prior to application of the periosteal flap, microfractures in the subchondral bone are created to allow bone marrow cells access to the then-sealed cartilage defect in an attempt to utilize the stem cell population in the bone marrow to regenerate the damaged cartilage. With autologous chondrocyte implantation, a biopsy of cartilage tissue is removed from the patient prior to surgery and cultured *in vitro* to obtain a large chondrocyte population that is then injected back into the periosteal flap-sealed cartilage defect. In the case of osteochondral

autografting, a series of osteochondral plugs consisting of cartilage, the underlying subchondral bone, and the tide-mark region separating them are removed from a nonloading region at the edge of the damage joint. These plugs are then implanted into the primary cartilage defect using an approach termed *mosaicplasty*, named after the mosaic pattern of the implanted osteochondral plugs (Capito and Spector, 2003). These procedures, however, exhibit limited long-term success in treating the cartilage injury. Preclinical studies implementing tissue-engineering approaches have yielded results that represent improvements over the currently employed cartilage repair procedures.

Various synthetic and natural materials have been employed to fabricate porous, bioresorbable scaffolds for articular cartilage tissue engineering. Among the list of bioresorbable or partially resorbable materials used for cartilage repair are collagen, hyaluronan, fibrin, polylactic acid (PLA) and polyglycolic acid (PGA), chitosan scaffolds and gels, devitalized cartilage, hydroxyapatite, demineralized bone matrix, and bioactive glass (Capito and Spector, 2003). Natural polymers, such as collagen, provide a more native surface to cells and have been the primary focus of tissue-engineering studies due to previous successes in peripheral nerve and skin regeneration. Studies have confirmed that the addition of cells seeded within these 3D scaffolds enhance matrix synthesis and increase type II collagen production *in vivo* and *in vitro* (Capito and Spector, 2003; Kinner *et al.*, 2005; Lee *et al.*, 2003). Various cell types may be used to enhance cartilage synthesis when seeded into matrices, including articular chondrocytes and chondroprogenitor cells derived from bone marrow, periosteum, or perichondrium (Capito and Spector, 2003; C. R. Lee *et al.*, 2003).

Preliminary investigations have been focused on the bioactivity of chondrocytes in a series of ECM analogs. Promising results have been observed for adult articular chondrocytes cultured *in vitro* in type II collagen–glycosaminoglycan (CG) scaffolds, where the chondrocytes have retained high biosynthetic capacity for producing type II collagen, the predominant ECM component of cartilage (Capito and Spector, 2003; C. R. Lee *et al.*, 2001). Type II CG scaffolds seeded with autologous, articular chondrocytes have also been evaluated for their *in vivo* regenerative capacity in a full-thickness cartilage injury model; the full-thickness cartilage injury, with cartilage removed down to the subchondral bone, is the standardized, anatomically well-defined wound utilized for *in vivo* studies of cartilage regeneration. The greatest total amount of reparative tissue was found in the cell-seeded type II CG scaffolds, as opposed to unseeded type II CG scaffolds and seeded or unseeded type I CG scaffolds. Moreover, examination of the reparative tissue formed in the subchondral region of defects treated with the chondrocyte-seeded type II collagen scaffolds indicated that the majority of the tissue was positive for type II collagen and that good integration was observed between

the implant and the surrounding cartilage. These results indicate an influence of the exogenous chondrocytes on the process of chondrogenesis (Nehrer *et al.*, 1998). Such studies of the healing of chondral defects in animal models have revealed that there is some potential for regeneration of this connective tissue. The introduction of certain biomaterial scaffolds along with selected surgical procedures and cell therapies has been demonstrated in animal studies to facilitate the cartilage reparative process and now offers the promise of extending the longevity of clinical treatments of cartilage defects (Kinner *et al.*, 2005; C. R. Lee *et al.*, 2003; Samuel *et al.*, 2002).

In a separate series of studies, the regenerative potential of chondrocytes encapsulated in photopolymerized poly(ethylene oxide) hydrogels and self-assembling peptide hydrogels has been tested using an *in vitro* culture model followed by *in vivo* implantation. Preliminary results suggest that photo-cross-linked (Bryant and Anseth, 2001) and self-assembling hydrogels (Kisiday *et al.*, 2002; Zhang *et al.*, 1993) are promising scaffolds for tissue-engineering cartilage, for cell viability was maintained, uniform cell seeding was achieved, and the biochemical content of the ECM proteins synthesized within the construct were similar to those found in native cartilage (Bryant and Anseth, 2001; Kisiday *et al.*, 2002). Additionally, the importance of the biomechanical environment during *in vitro* culture of chondrocytes within a three-dimensional construct has been observed. Improved biosynthesis of ECM components, notably native proteoglycans, is observed when a cyclic loading environment is applied to *in vitro* chondrocyte cultures within a series of hydrogel and scaffold constructs (Kisiday *et al.*, 2004).

Collectively these findings provide the basis for the rational development of approaches for the more complete regeneration of articular cartilage and demonstrate that meaningful clinical outcomes can be achieved even if complete regeneration is not achieved (Kinner *et al.*, 2005; C. R. Lee *et al.*, 2003; Samuel *et al.*, 2002).

## VII. CONCLUSIONS

Following severe injury, the typical physiological response is characterized by a complex inflammatory response, cell-mediated wound contraction, and scar tissue synthesis characterized as repair. However, introduction of a suitable analog of the extracellular matrix into the wound site has been observed to block cell-mediated contraction of the wound site and to induce regeneration of physiological tissue. Although several ECM analogs have been studied, only those with a narrowly defined structure have been shown to be capable of regeneration. The microstructural, chemical compositional, and biodegradation rate specificity of these templates appears to be related to the requirement for inhibition of wound contraction prior to the incidence of regeneration. A number of appropriate materials have been developed and tested for use in particular *in*

*vivo* wound sites, notably the skin, peripheral nerve, conjunctiva, and cartilage. The results of *in vitro* and *in vivo* investigations of many biomaterial constructs suggest that the properties of an ECM analog must be tailored to the

specific wound site and species, requiring further development of appropriate *in vivo* and *in vitro* models to further understand the complexity of cell–scaffold interactions and the process of induced regeneration.

### I. INTRODUCTION

Work *in vitro* with intact tissues or tissue fragments in the form of organ cultures has had a long history in developmental biology in studies devoted to causal relationships between tissues on which the emergence of differentiated structures depend. Before the discovery of pluripotent embryonic stem cells and adult mesenchymal stem cells it was believed that, while monolayer cell cultures usually lost the characteristic histological organization and most of the physiological functions of the original tissue, organ cultures retained both and permitted the process of development to unfold. But organ culturing, unlike cell culturing, consists of explanting organ anlage or pieces of intact tissues under conditions that preserve tissue integrity and discourage cells from moving out of the explant and from engaging in DNA synthesis that leads to cell division. The disadvantages of organ cultures include their short life, particularly when adult tissues are explanted, their tendency to undergo central necrosis, the occurrence of vascular occlusion, and the difficulty of preparing reproducibly standard models. Nonetheless, in retrospect, stability of the organ cultured

explant was attributed, in large measure, to the matrix scaffolds with which the cells in tissues were associated.

As long ago as 1963, Dodson, in Honor Fell's laboratory in Cambridge, England, was concerned with the role of scaffolding in studies of tissue interactions *in vitro*. He isolated dermis from the metatarsus of 12-day chick embryos and subjected it to freeze-thaw cycles before combining it with epidermis that alone was unable to differentiate (Dodson, 1963). Although it lacked living cells, the frozen-thawed dermis, constituting a structurally intact collagen scaffold, and probably rich in growth and differentiation factors, was sufficient to support keratinocyte differentiation *in vitro*. A control, consisting of heat-killed dermis, failed to promote keratinocyte differentiation. Similar combinations using adult acellular dermis and keratinocytes made many years later (Heck *et al.*, 1985; Cuono *et al.*, 1987) were used successfully as transplants to patients requiring skin.

Now we believe that what cells did in organotypic explants, as *in vivo*, was regulated by instructive scaffolds and cell signaling. The use of media unsupplemented with growth factors and containing high concentrations of serum

may have had a detrimental effect on signal-induced differentiation. The development of low-serum or serum-free media has significantly improved the value of *in vitro* models as well as the effectiveness of their use as remedial implants *in vivo* (Boyce and Ham, 1983).

An alternative approach to the study of tissue interactions *in vitro* consists of reconstituting each of the tissues with scaffolds into which cells of one or more interrelated tissues of an organ are seeded (Bell *et al.*, 1979). The field of tissue engineering had its beginning in our lab at MIT in the late 1970s. We realized nearly immediately that a source of stemlike cells was required for tissue propagation, both for research and particularly for products designed for clinical use. For that reason we elected to focus first on skin, a self-renewing tissue whose principal cells, dermal fibroblasts and keratinocytes, were capable of dividing and of expressing their phenotype for at least the life span of the human organism. To maximize their functional life span it made sense to choose newborn foreskin as a starting source for cells. Foreskin is often a discard tissue, coming mainly from newborns. The focus now on the use of stem or “stemlike” cells to develop tissue or organ equivalents for *in vitro* analysis or for subsequent transplantation has sharpened with the discovery of multipotent mesenchymal stem cells in the postnatal human organism (Pittenger *et al.*, 1999) and the discovery of pluripotent embryonic stem cells (Thompson *et al.*, 1998).

For tissue engineering the second key requirement was that of selecting an appropriate matrix scaffold recognizable and remodelable by the cells that would be seeded into it. The requirements for the original scaffold selected were based on the bias that what has evolved in nature might be imitated *in vitro*. We are still not sure that conditions exactly similar to those exhibited by a collagen gel prevail *in vivo* in early tissue formation in the embryo. References and a discussion of the role of the extracellular matrix appear in a paper on strategy for the selection of scaffolds for tissue engineering (Bell, 1995). The subject is touched on in a book on the organization of the extracellular matrix (ECM) (Modis, 1990). The author uses a polarization microscope to describe the ECM (p. 178), seemingly comparing a collagen gel to what he sees *in vivo*. He states: “Collagen gel shows parameters that are more similar to those observed *in vivo*.” Unfortunately, he elaborates no further. Since the assembly of collagen fibrils and fibers can be visualized with the polarization microscope, it would be possible to provide a detailed description of the cell-directed organization of the early dermis compared with what cells do in a contracting collagen gel. We considered ideal properties for the scaffold to be the following: (1) that it have binding sites normally used by the cells that populate it, and (2) that it have, or come to have, the structural organization cells need for their orientation. These are cues that dictate tissue design, on which function depends. We found, for example, that if two opposite edges of a forming dermis were constrained, the force field created by cells as they collected collagen fibrils in the

gel, causing fluid to be expressed from the gel, resulted in cell polarization. The long axes of cells and the forming collagen fibers became oriented in parallel with the lines of force between the constrained edges of the gel. We underscore that *in vitro* models might well be designed to incorporate physical forces that act on scaffolds and cells, contributing to their full developmental potential. An early relevant paper appeared shortly after we reported on formation of a dermal equivalent. The authors developed a model system using distortable sheets of silicone rubber on which they plated various types of cells to measure the relative strengths of traction exhibited (Harris *et al.*, 1981).

Coculturing interactive tissue-specific subsets of cells, such as the two principal phenotypes that make up skin, in an appropriate scaffold is reviewed later as *in vitro* models for studying disease states, bioprocesses such as melanogenesis, the immunogenicity of engineered tissues, and wound healing. Other factors may be implicated in extracellular matrix remodeling. Platelets and platelet lysate up-regulate collagen gel contraction *in vitro* as a function of time and concentration. Release of PDGF-AA/AB and TGF- $\beta$  from platelets partially mediates the increased gel contraction (Zagai *et al.*, 2003). We keep in mind that living-skin equivalent (LSE) was the first tissue-engineered product to make its way into the medical market and should be considered an early product subject to improvement. We also attempt to cover several other models by tissue type and to touch on some of the biomaterials and techniques used for engineering scaffolds.

The first LSE consisting of “living” dermis and epidermis was made up of fibroblasts and keratinocytes derived from foreskin. The dermal fibroblasts contracted the collagen gel scaffolding (Bell *et al.*, 1979; Bell *et al.*, 1991) making it tissue like. The time required to construct a skin model was 14–21 days, in the course of which at least three different media were used. First, an initial medium supports the contractile activity of dermal fibroblasts. The dermal cells are responsible for compacting the starting collagen lattice by attaching podial processes, to collagen fibrils and withdrawing the processes, with the attached fibrils toward the cell body. As a result of these local contractions, fluid is expressed from the collagen lattice, and the volume of the lattice diminishes by a factor of 30–40 until an equilibrium size is attained and no further contraction occurs. The volume reduction is related to the number of cells used and the concentration of collagen (Bell *et al.*, 1979). Second, another medium is applied at the time of keratinocyte plating when skin is being fabricated, since the first phase of epidermal development, keratinocyte proliferation, requires low  $\text{Ca}^{++}$ , EGF, and an up-regulator of cyclic AMP. A third medium is used during the second phase of epidermal development, calling for high  $\text{Ca}^{++}$  and air-lifting to expose the epidermis to the atmosphere to promote keratinization and differentiation of a stratum corneum (Bell *et al.*, 1991; Parenteau *et al.*, 1991).

The LSE was shown to undergo virtually complete differentiation *in vitro*, lacking, however, pigment, sweat glands, neurogenic elements, a microcirculation, and hair follicles. The model was reproduced faithfully and kept alive *in vitro* for months, at least. Although collagenolytic activity is high in young dermal equivalents, it has been observed that the resistance of dermal equivalents to breakdown by collagenase is greatly enhanced by 30 days of cultivation *in vitro*, suggesting that extensive cross-linking of the collagen fibrils by cell-secreted lysyl oxidase has occurred, as shown by Rowling *et al.*, 1990. Continued differentiation of the skin equivalent model *in vitro* and the resemblance of differentiated cells in the matrix to their *in vivo* counterparts, rather than to cells grown on plastic in two dimensions, are distinguishing features (Coulomb *et al.*, 1983). Collagen processing by cells grown on 2D substrates is known to be deficient, in that the exported molecule retains the pro-collagen C- and N-terminal telopeptides normally cleaved by peptidases (Freiberger *et al.*, 1980). In the collagen lattice scaffold, processing and subsequent polymerization, for which it is a requirement, proceed normally (Nusgens *et al.*, 1984).

Aware of the potential of using embryonic stem cells (ESC) (Thompson *et al.*, 1998) as a source of cells for the tissue engineering of skin, we have looked for publications announcing successful induction of either the dermal fibroblast or keratinocyte phenotype or both in ESC. Some early efforts may need further trials. For example, a paper dealing with the subject reports reconstituted skin from murine ESC. Keratinocyte differentiation was prompted by use of ECM secreted by primary cultures (Soraux *et al.*, 2003). It was not stated that ESC were harvested from the blastula's inner cell mass, nor are the putative ESC shown to proliferate for many doublings without differentiating, nor was it shown that the genotypes of the differentiated skin cells were the same as that of the ESC. Rigorous criteria laid down by Thompson need to be observed. There appear to be no reports that postnatal mesenchymal stem cells (MSC) can be induced to express either skin phenotype. The seminal paper by Pittenger *et al.*, 1999 lists the lineages into which adult human MSC can be induced to differentiate, consisting exclusively of adipocytes, chondrocytes, osteocytes, tendon, muscle cells, and marrow stroma. Subsequent reports suggest that the repertoire of MSC can be expanded to include neural cells [in the mouse, for example (Croft and Przyborski, 2006; Hong *et al.*, 2006)]. Croft and Przyborski suggest that trans-differentiation may occur as a result of culture conditions for cells under test *in vitro*. The cells spontaneously express neuronal phenotypic markers in culture, and, when implanted into the lateral ventricles of the neonatal mouse brain, they differentiate into olfactory bulb granule cells and periventricular astrocytes. The foregoing work and related papers suggest that the full range of potential phenotypes of MSC has yet to be realized.

In the light of what appear to be expanding cell sources in adult organisms hopefully available for use in reconstitut-

FIG. 17.1.

ing needed prosthetic devices, there is optimism that adult organisms have reservoirs waiting to be tapped. Reported sources of progenitor endothelial cells in bone marrow and blood (Asahara *et al.*, 1997; Shi *et al.*, 1998; Lin *et al.*, 2000; Asahara *et al.*, 1999; Kalka *et al.*, 2000; and Peichev *et al.*, 2000) and of smooth muscle from the same sources (Shimizu *et al.*, 2001) bring the prospect of populating arterial scaffolds closer to clinical reality.

Reports of other sources of multipotent stem cells have been surfacing. Of interest have been preliminary discoveries that adult stem cells from rodent dermis have the capacity to proliferate and differentiate *in vitro*. Evidence was gathered (Toma *et al.*, 2001) that neural, smooth muscle, and adipocyte phenotypes arose in clonal cultures *in vitro*. A similar finding in glabrous fetal human skin, that dermal cells can give rise to a broad range of phenotypes each having been induced by undefined tissue-specific signals, was published several months later (Dai *et al.*, 2002). The phenotypes induced included the following: cartilage, liver, lung, heart, endocrine pancreas, smooth muscle, and bone.

However, we point out that the ease with which strains of skin cells can be established from foreskins has already been shown by the company Organogenesis to be ample for the commercialization of skin products for medical use. Much emphasis has been placed on markers that identify skin stem cells, particularly keratinocytes. Keratin-19 (K-19) as a marker of stem cells was found to be expressed at glabrous sites, such as foreskin in deep epidermal rete ridges (Michel *et al.*, 1996). Cells expressing K-19 were also rich in alpha-3 beta-1 integrin. K-19 positive cells were more numerous in newborns as compared with older foreskins. The subject of keratinocyte stem cell markers has been reviewed and covered in a number of key papers (Watt, 1998; Lavker and Sun, 2000; Pellegrini *et al.*, 1999; Li *et al.*, 1998).

Populating matrix scaffolds, other than collagen lattices (gels), with dermal fibroblasts to produce dermal equivalents followed the introduction of the original work that reported the fabrication of both dermal and skin equivalents (Bell *et al.*, 1979, 1981). Materials used include Vicryl (Hansbrough *et al.*, 1993) and Biobrane (Hansborough *et al.*, 1994). For example, there is the commercial product Derma-graft, no longer being manufactured by Advanced Tissue Sciences but adopted by Smith and Nephew. The product was made using the technique of seeding the Vicryl scaffold with allogeneic dermal fibroblasts, first shown to be possible in fibroblast-contracted collagen gel scaffolds covered by differentiating epidermis in animal experiments by Bell and colleagues at MIT. See Table 17.1 for a list of collagen-based products for skin replacement and/or repair.

The company Organogenesis, founded by Bell *et al.*, conducted extensive animal trials and human clinical trials of the living-skin equivalent before the commercial product, called Appligraf™, was launched, and they confirmed the early rat trials by Bell and his group carried out at MIT (Sher *et al.*, 1983). In a collaboration with Dr. Jack Gaisford at the Western Pennsylvania Hospital in Pittsburgh it was found that the living-skin equivalent performed poorly when applied to burned skin. The prosthesis began to degrade in a matter of days. This response did not discourage us, because of the known difficulties of replacing badly burned skin. Dr. Gaisford's continuing interest was unflagging. He had raised capital for support of the work at the Western Pennsylvania Hospital and continued to do so for the newly formed Organogenesis. Organogenesis continued the MIT experiments with animals and, with Dr. Gaisford, carried out the first trials in humans. These took place before Appligraf was approved by the FDA and launched commercially. In the course of extensive patient use for curing ulcers and for use on donor sites it was established that the living-skin equivalent had significant remedial value and that, being built with both allogeneic fibroblasts and keratinocytes, from which donor immune cells are deleted, it did not provoke a rejection response, confirming the early rat trials carried out by Bell and his group at MIT.

## II. PIGMENTATION OF THE LIVING-SKIN EQUIVALENT (LSE) *IN VITRO*

Neonatal melanocytes cultured from foreskin have been incorporated into the living-skin equivalent (Topol *et al.*, 1986) by plating them on the cell-populated contracting dermal equivalent before the application of keratinocytes. Punch biopsies (2 mm) of unpigmented foreskin were overlaid on the dermal equivalents after third-passage melanocytes were added to it. By 14 days the dermal lattice was covered by keratinocytes. By that time a basal lamina developed at the dermal-epidermal junction *in vitro*. The procedure led to skin pigmentation *in vitro*, as pigment was donated by melanocytes to keratinocytes. Exposure of some

living-skin equivalents to UVB irradiation for 14 days stimulated and enhanced pigment transfer. Pigment transfer was documented by light and electron microscopic studies. Donated melanosomes, identified by their pigment as well as by dopa-oxidase staining, were found dispersed throughout the cytoplasm of the keratinocytes.

## III. THE LIVING-SKIN EQUIVALENT AS AN IMMUNOLOGICAL MODEL

The LSE is constituted with cultivated parenchymal cells free of any subsets of immune cells normally found in the dermis and epidermis. Using the X chromosome as a genetic marker, LSEs made up with female cultivated rat cells were transplanted to male rat hosts across a major histocompatibility barrier (Sher *et al.*, 1983). Allografted fibroblasts were accepted by recipient rats after a transient mononuclear cell response, as shown by cell karyotyping. LSEs containing xenogeneic fibroblasts were rejected. A second LSE allograft from the same donor strain did not provoke rejection, either of the original allograft or of the challenge allograft. In a further experiment a secondary graft of allogeneic skin did not provoke rejection of the original skin, while an actual skin graft was rejected. In an additional control, grafting the recipient first with actual allogeneic skin and then with the LSE allograft led to rejection of the actual skin but not of the LSE graft, ruling out the possibility that suppressor T-cells were responsible for LSE allograft acceptance. It can be said, then, that allografted fibroblasts do not provoke a rejection response, even in pre-sensitized animals, that they do not render the recipient tolerant to allogeneic skin, and that they do not act as targets when active rejection is taking place. We propose that cells bearing class I antigens generally may be acceptable as graft constituents if incorporated in tissue equivalents excluding cells bearing class II antigens. Similar results in humans have been reported by Organogenesis Inc. using *in vitro* cultivated cells. Clinical trials of living-skin equivalents made up with human allogeneic keratinocytes do not provoke an immune reaction in recipients (Parenteau *et al.*, 1994). The model should be a valuable tool for determining the roles played by cells of the immune system and micro-circulation in allograft rejection of actual skin. It should allow use of cells of any genotype and of human origin to study genetic abnormalities as well as the contribution of specific genes to skin development by transplanting skin equivalents to immunodeficient organisms.

## IV. THE LIVING-SKIN EQUIVALENT AS A DISEASE MODEL

Since either normal or aberrant skin cells can be incorporated into living-skin equivalents, models of disease states can be fabricated. A psoriasis model was fabricated to test the contribution of psoriatic dermal fibroblasts to the expression of features of the disease *in vitro* (Saiag *et al.*,

**Table 17.1.** Collagen-based products for skin replacement or repair

<i>Name</i>	<i>Manufacturer</i>	<i>Composition</i>	<i>Indications</i>	<i>Incorporated into wound bed?</i>
Promogran®	Johnson & Johnson	Animal collagen (55%) and oxidized regenerated cellulose	Most partial- and full-thickness wounds	No data
PuraPly®	Royce Medical	Porcine type I collagen	Most partial- and full-thickness wounds, including chronic wounds, donor cites, and MOHS surgery	No data
Fibrocol Plus®	Johnson & Johnson	Denatured animal collagen (90%) with alginate (10%)	Partial-thickness wounds, venous ulcers, acute traumatic wounds, second-degree burns	No data
Integra®	Integra Life Sciences	Collagen-glycosaminoglycan copolymer matrix coated with polysiloxane elastomer	Grade I–III noninfected ulcers that involve tendon, bone, joint. Full-thickness burns	Incorporated within 2–3 weeks
OrCel®	Ortec International	Collagen sponge that contains allogeneic living skin cells	Epidermolysis bullosa, skin graft donor sites, venous and diabetic foot ulcers	No data
EZ Derm®	Brennan	Porcine chemically modified xenografts	Partial-thickness wounds, donor sites, ulcers, and meshed autografts	Not incorporated and must be removed
OASIS®	Cook	Porcine xenograft (small intestinal submucosa)	Partial- and full-thickness wounds, ulcers, trauma, and surgical wounds	Incorporated within few weeks
APLIGRAF®	Organogenesis	Living bilayered skin substitute on type I bovine collagen matrix	Venous leg ulcers, diabetic foot ulcers	Incorporated within few weeks
AlloDerm	Life Cell	Human decellularized dermis	Soft tissue repair and reconstruction, abdominal wall repair, burns, and wound coverage	Incorporated within 2–3 weeks
PriMatrix™	TEI Biosciences	Fetal bovine acellular dermal matrix	Partial- and full-thickness wounds, ulcers, trauma and surgical wounds, general orthopedics, second-degree burns	Incorporated within 2–3 weeks
GRAFTJACKET®	Wright Medical	Human decellularized dermis	Soft tissue repair and reconstruction, abdominal wall repair, burns, and wound coverage	Incorporated within 2–3 weeks
GammaGraft®	Promethean LifeSciences	Irradiated human skin allograft	Partial- and full-thickness wounds, ulcers, trauma and surgical wounds, burns	Incorporated within few weeks
Mediskin	Novamedical GmbH	Fresh sterile porcine skin	Burns	Temporary, not incorporated, and must be removed

From: burnssurgery.org; *Podiatry Management*, June/July 2006.

1985). A button of normal keratinocytes was plated on the centers of dermal equivalent discs constituted with human normal or psoriatic dermal fibroblasts, and the rate of growth of the sheet of keratinocytes over the dermal substrate was measured. It was observed that the psoriatic fibroblasts induced hyperproliferation of keratinocytes as compared with the growth induced by control fibroblasts. In addition to the study of psoriasis and other epidermal diseases, such as epidermolysis bullosa, the model should provide an *in vitro* basis for studying disorders in dermal connective tissues, including dermatosparaxis and sclerosis. It is obvious that any pair of mesenchymal cells and epithelial cells of which one or both is diseased or aberrant can be used in the three-dimensional coculturing system for studying the expression of features of the disease.

## V. WOUND-HEALING MODEL

LSE models can be used *in vitro* to analyze the role of dermis in epidermal wound healing (Bell and Scott, 1992). After making a differentiated skin equivalent in a 6- or 12-well multiwell plate insert (24 mm, e.g.), a central disc of the skin is removed with a punch (Fig. 17.2). The acellular pad in contact with the membrane of the insert is replaced, and the remainder of the gap is filled with a collagen scaffold to the level of the interface between the dermis and epidermis. As the collagen scaffold is being populated by fibroblasts migrating into it from the surrounds, keratinocytes from the edges of the epidermis migrate over the neodermis and undergo differentiation. We suppose that the migrating epidermal cells are stem cells whose properties are waiting to be assessed. The rate of overgrowth of the neodermis by keratinocytes and the development of the epidermis can be

taken as measures of the effectiveness of neodermis as an interacting substrate. The model lends itself as an assay system for determining the effect of growth factors and other signals on each of the events of wound healing. The new scaffold developed at TEI Biosciences as an acellular skin replacement, called EBM after its discoverer, (commercially, it is called PriMatrix, which is a freeze-dried product) and discussed in detail later in the context of vascular prostheses, supports the overgrowth of epidermis from adjacent host tissue in a rat model. Note in Fig. 17.3 that in-growth of blood vessels is extensive, as is the growth and differentiation of overlying epidermis, which in the example shown has covered a circle 8.0 mm in diameter in one week. The neodermis is populated by dermal fibroblasts and other cells. The EBM material is now in the market.

Generic models for many types of epithelial-mesenchymal combinations were reported in the early years of tissue engineering. Some of the combinations for organotypic coculturing are the following: for skin references (Bell *et al.*, 1979, 1981; Topol *et al.*, 1986); for cornea reference (Minami *et al.*, 1993); for blood-brain barrier references (Bell *et al.*, 1990; Beigel and Pachter, 1994); for gut reference (Montgomery, 1986); for vessel references (Weinberg and Bell, 1986); for nerve tissue references (Guthrie and Pini, 1995; Bergsteinsdottir *et al.*, 1993; Tomooka *et al.*, 1993); for capillary network references (Mori *et al.*, 1989); for pancreatic islet references (Lanza *et al.*, 1995; Soon-Shiong *et al.*, 1993); for hair follicle references (Watt, 1998); for thyroid gland references (Bell *et al.*, 1984). Many others are of course possible. We are not suggesting that combinations need be restricted to epithelial-mesenchymal combinations. For example, interactions between subpopulations that are coderivatives embryologically can also be modeled in a 3D system *in vitro*. In the development of the nervous system, both attractive and repellent signals guide the course of axons en route to endpoint targets (Guthrie and Pini, 1995). The authors of the foregoing citation seeded a collagen gel

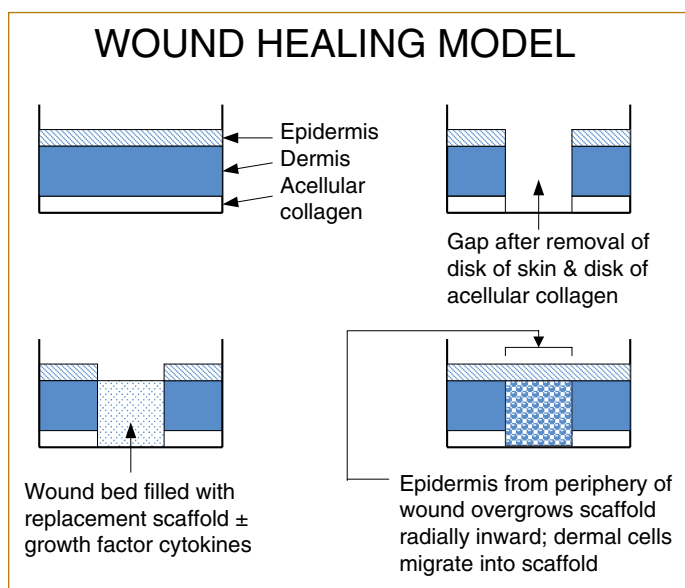

FIG. 17.2.

FIG. 17.3.

scaffold with two components, either ventral explants of rat hind brain or spinal cord and floor plate explants from which the former tissues were separated in the scaffold gel. It is shown that outgrowth of motor axons from aspects of hind brain or cord that faced the plate were greatly reduced, suggesting that diffusible factors from the floor plate can exclude motor axons from certain regions of the developing nervous system. The existence of chemorepellents as well as attractants has been discussed recently (Marx, 1995). They divide into at least two families of proteins, nestins and semaphorins, responsible for growth cone guidance. It is suggested that a single factor can induce attraction or repulsion, depending on the cells involved.

## VI. VASCULAR MODELS WITHOUT CELLS

Vascular prostheses constructed from Dacron and other synthetics have been in use for many years but are known to elicit persistent inflammatory reactions and to become occluded. The thermosetting polymers are not biodegradable and do not integrate with host tissues, but some successes have been reported under limited conditions in experimental animals (Sandusky *et al.*, 1992; Leenslag *et al.*, 1988; Stronck *et al.*, 1992). For the foregoing reasons and because the synthetics do not come to life, other materials have been proposed and tried as arterial substitutes. Animal tissues that resemble arteries have been used with some success, in particular the porcine small intestine (Sandusky *et al.*, 1992). The mucosal cells are scraped off the luminal side, and the muscular layers are removed from the abluminal side, leaving the stratum compactum, a dense, highly organized fibrillar collagen matrix, and the looser connective tissue of the mucosa. The material can be used as a scaffold for cells *in vitro* and has been used in animal experiments. Implanted *in vivo* without cells it is invaded by capillaries, which, it has been claimed, contribute cells that provide an intima, and, similarly, smooth muscle cells migrate from the anastomoses to provide a media.

Using engineered vessels made up of air-dried EBM wrapped onto a sutured tube-shaped vessel, we began a program of testing it in a closed circulatory loop through which saline and/or human blood was pumped under physiological conditions at a pressure of 90 mmHg. While the air-dried EBM itself was impermeable, the tube leaked at the suture holes and between the layers of the doubly wrapped tube (experiments were conducted by V. Russakovsky,\* T. Fofonoff,\* and E. Bell at TEI Biosciences Inc.).

## VII. VASCULAR MODELS WITH CELLS ADDED

Vascular models that examine the effect of shear and other forces on monolayers of endothelial cells *in vitro* have been developed by Nerem *et al.*, 1993, who have shown that the rate of endothelial cell proliferation is decreased by flow and that entry of cells into a cycling state is inhibited. They point out the limitations of the 2D system, since the

important component of cyclic stretch of basement membrane, which the endothelium normally synthesizes and on which it rests, is absent. They suggest that a coculture system in which the endothelium is supported on smooth muscle tissue would be superior for providing a more physiological environment. Such a system was developed by Weinberg and Bell, 1986, who showed that a basal lamina was laid down between the endothelium and the contiguous smooth muscle tissue cast in the form of a small-caliber tube *in vitro*. Fabricating the vessel was a three-step procedure.

The first tissue layer cast around a small-caliber mandrel was a smooth muscle cell media whose ends were anchored in a Velcro cuff or held fast by ridges and grooves in the mandrel until radial contraction made space for bands that were secured around the ends. Hence the mechanical restraint imposed on the contracting tube allowed contraction to occur radially, but not longitudinally, since each end of the vessel equivalent was held fast. The second tissue layer cast was the adventitia surrounding the smooth muscle media. To make room for it, the fluid expressed from the collagen gel scaffold was drawn out of the casting tube, and the mixture of adventitial fibroblasts suspended in medium containing neutralized collagen was introduced into the space between the media and the wall of the cylindrical casting chamber. After the adventitia had contracted radially, but not longitudinally, since the media provided a frictional surface, which prevented it, the mandrel was extracted, leaving the lumen of the tissue tube empty. The lumen was then filled with a suspension of endothelial cells. The cells came to rest on the inner surface of the media as the tube was rotated.

Histological analysis showed that the smooth muscle cells of the media were oriented in parallel with the long axis of the tissue tube that had formed, rather than circumferentially as they dispose themselves *in vivo*. By modifying the foregoing procedure the vessel was allowed to contract freely in its length (L'Heureux *et al.*, 1993; Hirai *et al.*, 1994). That is by eliminating the restraining ties at the ends of the mandrel, the smooth muscle cells oriented circumferentially as they do *in vivo*. Similar results are obtained by applying pulsatile pressures, causing the media of the vessel to expand radially (Kanda *et al.*, 1993). Another method (Tranquililo *et al.*, 1996) is based on the observation that polymerizing collagen fibrils align in magnetic fields (Torbert and Ronziere, 1984). By orienting the model devised by Weinberg and Bell, in which the ends of the developing vessel are tethered, with its long axis parallel to a strong magnetic field during fibrillogenesis, it has been shown that collagen fiber orientation is circumferential. The fiber orientation provides contact guidance for smooth muscle cells that encircle the vessel in a direction perpendicular to its length. We found that the more normal organization of the cells of the media reduces the excessive compliance of the structure that resulted from the longitudinal orientation of the smooth muscle cells.

The cell-seeded arterial blood vessel equivalent has been steadily evolving. In the course of early animal trials, we concluded that the collagen gel lattice does not provide the structural resistance typical of an actual artery, and we resorted to the use of synthetics to provide added strength. We think now that the stratagem was not useful, because the synthetic structure, designed to provide strength, does not satisfy the binding- and substrate-dictated cell orientation needs of medial or adventitial cells (Weinberg *et al.*, 1993). We were then led to try a new tissue-engineering approach that incorporates aspects of issued patents and patents pending. We have been developing and using products in the market, various versions of EBM (U.S. Patent #6,696,074 — issued 2004), made up from bovine fetal embryonic skin harvested before hair follicle differentiation. In addition, for the new version of the vessel we have been using various types of spun collagen threads (U.S. Patents: #5,562,946, #5,851,290, #5,911,942, #6,705,850 B1). To prepare a vascular prosthesis, a layer of hydrated collagen threads is spun spirally around a mandrel of the diameter of the vessel to be produced. The spirals are then freeze-dried. When populated by cells, the freeze-dried threads provide the orienting substrate for smooth muscle cells, which dispose themselves perpendicularly to the long axis of the vessel. We refer to some of the history of work concerned with the organization of smooth muscle cells in the media of arterial vessels. In order for the cells to contract the vessel radially and then to relax to allow for vessel expansion, they must be oriented circumferentially. What we are describing now is yet another method for directing the desired disposition of cells in a prosthesis.

Back to the incorporation of processed sheet EBM into the vessel being formed. The EBM is designed to endow the vessel with the strength it requires. The tensile-breaking strength of unmeshed EBM is ~25 MPa, while the breaking strength of 1/1.5 meshed EBM using a Zimmer Skin Graft Mesher machine is ~16 MPa. The meshed EBM is wrapped around the spiral thread layer so that the edges of the sheet meet exactly. It is then sewn longitudinally, making an EBM cylinder adhering tightly around the subjacent spiral thread layer, the layer to be seeded with smooth muscle cells. After sterilization, a solution of the desired concentration of cells, medium, and collagen, of a concentration able to form a gel, is prepared, and the mandrel with its acellular wraps is inserted and held centrally in a cylindrical tube containing a total volume that will form a thin gel when contracted by medial cells after the tube is transferred to a bath sterile, where the sealed tube is rotated for a period of 1 h at a temperature too low to allow gelling of the collagen but long enough to be populated by the cells that will make up the media of the vessel. After allowing cells to populate the collagen fibers, the tube is transferred to a 37° incubator, where it is again rotated while the collagen gel forms. After gel

formation, the tube is oriented vertically and the stopper of the tube is exchanged for one that admits CO<sub>2</sub> sterilely. The new vessel, built by methods described earlier, is currently under test. Results are expected to be published shortly.

In using multipotent stem cells in *in vitro* models, the requirements for inducing expression of a specific phenotype include a sequence of molecular signals, a matrix of extracellular design populated by the cells, and physical forces to which cells and matrix are subjected that modulate tissue development. Needed as well are the medium or media, growth factors, and other conditions of culture to promote cell growth and differentiation and tissue building, *in vitro*. The foregoing should lead to the fabrication of standardized models that closely resemble actual tissues in many respects. A generic model of two different tissues, that is, an organotypic system, is shown in Fig. 17.1. A collagen scaffold is seeded with mesenchymal cells, which condense it, together providing a substrate on which epithelial cells, such as keratinocytes, are plated.

## VIII. CONCLUSIONS

One of the major goals of model tissue building is the reconstitution of tissue or organ equivalents that faithfully resemble actual body parts in order to better understand cell and tissue function under controlled and reproducible conditions. From this point of view the model offers an opportunity to study disease states and to seek remedies for them. The model can also serve as a test system for toxicity testing, instead of depending on the use of animal cells. It has the advantage, when constituted with human cells, of giving responses to toxins that may be different from those of animal cells. Cells in organized tissue scaffolds exhibit reduced susceptibility to damage as compared with cells grown on a monolayer (Bell *et al.*, 1991). Other uses of model tissues, in addition to those detailed in this chapter, include diagnostic systems and cultivation of viruses that depend on cycling and differentiating cells.

Not least of all, as model building *in vitro* improves, so do prostheses for implantation in people. Model making and *in vitro* testing go hand in hand with testing in experimental animals. Model tissues can take many forms. (1) They can be seeded with parenchymal cells that normally populate the tissue being replaced; (2) they can be acellular but designed to mobilize cells from contiguous tissues after implantation *in vivo*; (3) they can be constituted with degradable biopolymer scaffolds that are permissive, with the expectation that the cells with which they are seeded or which populate them will create a tissue-specific extracellular matrix and associated scaffolding; or (4) they can be instructive, being provided with signals able to influence the activities of cells. The ultimate goal of tissue engineering is that of building replacement parts for people who need them.

### I. INTRODUCTION

A chapter on quantitative aspects of tissue engineering remains difficult to write at this point in the development of tissue regeneration and cell therapy processes. Although cell functional behavior and underlying molecular mechanisms are becoming increasingly amenable to quantitative approaches, incorporating these into the complex interactions among multiple cell types in organized tissue is currently beyond the scope of feasibility. A historical parallel may be drawn to the decades-long lag between the advent of the petrochemical industry and the useful introduction of rigorous analysis, in terms of fundamental physicochemical theories, decades later. Thus, it is clear that today's beginning attempts in tissue engineering must be highly empirical, with design based largely on intuition and experience, much like the petrochemical industry in the 1930s.

Following this parallel, however, it can be recalled that in the 1940s the concept of *unit operations* appeared, in which each particular chemical production plant could be broken down into some component processes that had some similarities to processes in different types of production plants. In this way, basic principles of chemical reactors, heat exchangers, material separation equipment, and so forth were elucidated in very simple quantitative terms. It was not that mathematical models for these unit operations were immediately combined into a comprehensive quantitative description of the entire plant — which is, of course, common practice today — but instead merely that

important design parameters of the components could be identified, and in some cases the direction of their manipulation for process improvement could be indicated.

This, then, appears to be the state of affairs for tissue engineering at the beginning of the 21st century: that key parameters governing components of the overall device or procedure might be identifiable, and some design principles for how they could be altered toward an improved device or procedure might be developed. In a manner analogous to the unit operations, simple mathematical descriptions of cell and tissue processes can be constructed for purposes of elucidating what properties matter and how they can be manipulated. This chapter therefore provides a brief overview of how major cell and tissue properties can be described and quantified in most basic form. These properties include molecular and cell transport through tissue, molecular interactions with cells, and tissue mechanics.

### II. MOLECULAR INTERACTIONS WITH CELLS

There are three main classes of molecules that must be dealt with in the context of cell interactions in tissue: soluble nutrients, soluble signaling molecules, and molecules associated with the extracellular matrix. The latter two classes interact with cells primarily via cell surface receptors, whereas the former class can either bind to cell surface receptors or pass directly across the cell membrane.

## Nutrients

For nutrient molecules that pass directly across the cell membrane — either by passive diffusion or via carrier proteins — such as oxygen, glucose, and amino acids, the kinetics of uptake and metabolism generally follow a Michaelis–Menten type of dependence. That is, at low concentrations the rate is first order in concentration, but as concentration increases the rate asymptotically approaches a constant plateau. In combination with transport rates through tissue, as described later, the consumption of nutrients can be analyzed in a fairly straightforward manner. If transport is modeled as simple diffusion through a medium in which cells are embedded as point sinks, the nutrient concentration distribution,  $L(x)$ , in the tissue is governed by the combined diffusion/reaction equation:

$$\frac{\partial L}{\partial t} = D \frac{\partial^2 L}{\partial x^2} - \frac{\rho k L}{K_M + L} \quad (18.1)$$

where  $D$  is the diffusion coefficient,  $k$  is the maximal uptake rate constant per cell,  $K_M$  is the saturation constant,  $\rho$  is the cell density, and  $x$  is the spatial distance from the source. For simple nutrients, the source is typically the bloodstream. Significant depletion of nutrient, and hence possible nutrient deprivation, will occur when the ratio of uptake to diffusion becomes small. This ratio can be usefully expressed in terms of the Thiele modulus:  $\phi = (\rho k X^2 / D)^{1/2}$ , where  $X$  is the overall distance from the source — for simple nutrients, this can be considered the mean distance between micro-circulatory blood vessels (this is an approximate expression, assuming that the uptake rate is constant, with value  $k$ , throughout the tissue.) When  $\phi < 1$ , the steady-state nutrient concentration becomes significantly less than the exogenous level. Transplantation of cells within a polymeric matrix can often give rise to depletion of important nutrients from levels required for sustained cell viability, when  $\rho$  is great and  $X$  is large, because the implant is not adequately vascularized. Nutrient transport limitations have been examined both theoretically and experimentally for the important case of encapsulated cells (Colton, 1995).

## Growth Factors and Other Regulatory Molecules

Many molecules important in tissue engineering, however, cannot be dealt with quite so simply. Regulatory molecules, such as growth factors, along with nutrient carriers, such as iron-bearing transferrin, bind reversibly to plasma membrane receptors and are then internalized by the cell by means of invaginating membrane structures in a process known as *endocytosis*. The receptor/ligand complexes are carried to intracellular organelles termed *endosomes*, from which they are sorted to a variety of fates, including lysosomal degradation and recycling to the cell surface (see Fig. 18.1). This entire process, known as *trafficking*, is quite complicated, and the distribution of fates for a

**FIG. 18.1.** Schematic illustration of receptor/ligand trafficking.  $L$  is intact ligand,  $L'$  is undegraded ligand;  $R_s$ ,  $C_s$ ,  $R_i$ , and  $C_i$  are cell surface and intracellular free and bound receptors;  $k_f$  and  $k_r$  are receptor/ligand association and dissociation rate constants;  $k_{eR}$  and  $k_{eC}$  are internalization rate constants for free and bound receptors;  $k_d$  and  $k_{dR}$  are degradation rate constants for ligand and receptor;  $k_x$  and  $k_{xR}$  are recycling rate constants for ligand and receptor;  $V_s$  is the receptor synthesis rate.

particular ligand can vary quantitatively as a function of its concentration as well as some of its biochemical and biophysical properties.

In the absence of trafficking, and when there is only a simple one-step reversible binding process, kinetic mass action equations can be written for the number of bound and free surface receptors and their ligands ( $L$ ). At equilibrium, the number ( $C$ ) of receptors ( $R$ ) found in the bound state is given by the expression

$$C = \frac{LR_t}{K_D + L} \quad (18.2)$$

$R_t$  is the total number of surface receptors, constant only when trafficking processes are eliminated.  $K_D$  is the dissociation equilibrium constant, equal to the ratio of the receptor/ligand dissociation rate constant to the association rate constant:  $k_r/k_f$ . It is essentially the reciprocal of the receptor/ligand-binding affinity. Commonly, however, ligands can bind to multiple receptors on the surface of a given cell, or receptors can be found in various states possessing different ligand-binding affinities. The interested reader is referred elsewhere for a detailed discussion of how to treat these more complicated situations (Lauffenburger and Linderman, 1996).

However, trafficking is almost universally present under physiological conditions, and the overall dynamics of uptake and metabolism of ligands and their receptors are strongly influenced by internalization, degradation, and recycling. Kinetic mass action equations can be written for the set of events shown in Fig. 18.1, and the dynamics of ligands and receptors in the various cell and tissue compartments can

be thereby analyzed for purposes of understanding key design parameters (Lauffenburger and Linderman, 1996).

For instance, consider a molecular ligand delivered to a tissue at rate  $V_L$ . For ligands such as growth factors, the source may be other cells in the tissue — perhaps implanted cells expressing a desired growth factor — or a polymeric controlled-release device or the bloodstream. Assuming a spatially homogeneous source, the steady-state ligand concentration will be given approximately by (assuming, for simplicity, that receptor and ligand recycling are negligible) the expression

$$L = K_D \left( \frac{k_{eR}}{k_{eC}} \right) \left[ \left( \frac{\rho V'_R + k_{deg} k_{eR} / k_f}{V_L} - 1 \right) \right]^{-1} \quad (18.3)$$

where  $V'_R$  is the receptor synthesis rate per cell,  $k_{eR}$  and  $k_{eC}$  are the free receptor and bound receptor internalization rate constants, respectively, and  $k_{deg}$  is a rate constant for extracellular proteolytic ligand degradation.

Following Wiley (1985), the corresponding steady-state number of receptor/ligand complexes per cell, which typically governs the functional response, is then given approximately by

$$C = \frac{LR_{\max}}{K_{ss} + L} \quad (18.4)$$

$R_{\max}$  is equal to  $V'_R / k_{eR}$ , and  $K_{ss}$  is equal to  $k_{eC} k_f / [k_{eR} (k_r + k_{eC})]$ . Note the similarity in form to Eq. (18.2), which governs the number of complexes in the absence of trafficking. Thus, trafficking determines the number of available surface receptors and the effective ligand-binding affinity.

When ligand concentrations are not spatially homogeneous, then the local value of  $L$  at any spatial position within the tissue must be determined by including the effects of diffusion, as in Eq. (18.1). Here  $x$  would be the thickness of tissue away from the source. Moreover, in place of the simple metabolic uptake rate constant,  $k$ , the net dynamics of trafficking must be incorporated to account for ligand consumption.

Binding and trafficking rate constants can be measured in cell culture assays, using ligands labeled with fluorescent or radioactive tags. Descriptions of basic experimental procedures and corresponding methods of analysis can be found elsewhere (Lauffenburger and Linderman, 1996).

Extracellular matrix components can compete with cells for binding ligand, and in some circumstances they may serve as a reservoir due to the reversible nature of protein/protein association. At equilibrium, this binding can be characterized using an expression analogous to Eq. (18.2). Extracellular matrix components may exhibit binding interactions with cell surface receptors; when they are sufficiently immobilized by their linkage within the matrix, Eq. (18.2) again can represent these interactions in the simplest case. As with soluble ligands, though, more complicated interactions can arise with multiple receptors for different domains of a particular matrix component.

Expressions such as Eqs. (18.1)–(18.4) can be used to estimate the rate of ligand delivery required to maintain a desired level of cell surface complexes and/or free ligand concentration. The number of surface complexes typically is important for determining the cell functional response. We emphasize, though, that it is likely that the rate of ligand binding to receptors to form signaling complexes may govern cell responses as much as, or more than, the static level of complexes (Wiley, 1992). Quantification of the dependence of cell behavior on complex levels and dynamics, however, remains in its infancy at present. A small number of particular examples can be offered as guidelines, including proliferation responses of fibroblasts to epidermal growth factor (Knauer *et al.*, 1984), leading to improvements in cell-level principles for growth factor design and delivery (Reddy *et al.*, 1996a, 1996b). A further level of complication in analysis arises from the presence of autocrine ligands in a wide spectrum of tissue physiological processes, though quantitative modeling and experimental studies are now being pursued on this aspect as well (Forsten and Lauffenburger, 1992; Lauffenburger *et al.*, 1998).

### III. MOLECULAR AND CELL TRANSPORT THROUGH TISSUE

Movements of molecular as well as cellular species through tissue is a vital aspect of most tissue-engineering processes, because the whole point of the intervention is to alter the composition of a local region from what it had been prior to the therapy. As mentioned earlier, transport of nutrients and regulatory factors into a cellular implant is generally required. Also, the goal of certain implanted devices is to release regulatory factors into the surrounding tissue. The synthesis of neotissues involves placing cells within a matrix composed of natural materials (e.g., collagen) or synthetic polymers (e.g., biodegradable templates). Within this environment, the cells also secrete and regulate the assembly of their own extracellular matrix, composed of collagens, proteoglycans, glycoproteins, and a variety of macromolecules important in cell–matrix and cell–cell interactions. Solute transport through this tortuous and often dense matrix plays a critical role in the maintenance of cell viability and in the successful growth and development of the intact tissue. Moreover, colonization of implants or grafts by cultured or host cells is often desirable. And, in some cell therapies, mainly those involving immune white blood cells, the movement of cells from an injection site into certain tissue regions is essential for them to carry out their intended functions.

#### Molecular Diffusion and Convection

Cell biosynthesis requires transport of low-molecular-weight metabolites and waste products, which occurs primarily by diffusion. Many other solutes play key roles as mediators of cell behavior and in cell production and turn-

over of extracellular matrix, including growth factors, hormones, cytokines, and endogenous proteinases and their natural inhibitors. Transport of regulatory factors can be crucial in tissue regeneration (Perez *et al.*, 1995) and can be reduced severely by interactions with matrix (Dowd *et al.*, 1999). In addition, the assembly of a physicochemically and mechanically functional matrix requires transport of newly synthesized matrix macromolecules to appropriate locations within the extracellular space. These matrix proteins and proteoglycans (as large as several megadaltons) have such low intratissue diffusivities that even slight fluid convection within the matrix can significantly enhance macromolecular transport (Garcia *et al.*, 1996).

In general, transport depends on the size and charge of the solute and on the density (tortuosity), water content, and charge of the matrix (Garcia *et al.*, 1998) (see Fig. 18.2). Although the principal modes of transport are molecular diffusion and convection (Deen, 1987), electrostatic interactions can also affect the partitioning and transport of charged solutes into and within a charged matrix (Grodzinsky, 1983). In this regard, it is useful to note that matrix charge density at the macroscale is often associated with the content of glycosaminoglycan chains attached to proteoglycans. At the scale of the cell, the dense, negatively charged glycocalyx at the surface of many cell types can also affect transport across the cell membrane.

Each cell and tissue type presents unique challenges for providing adequate transport in tissue-engineering design. For example, the density of cells in liver and kidney is typically much higher than that in connective tissues such as ligament, tendon, and cartilage. On the other hand, connective tissue cells grow within a very dense, hydrated, negatively charged matrix that may be several millimeters thick but with little or no vascular or lymph supply. Some cells are best grown on surfaces, whereas others require three-dimensional matrix encapsulation. The mechanical environment of cells also varies greatly: Vascular cells are subjected to fluid shear and to pulsatile stresses and strains within vessel walls; cartilage, bone, and other soft connec-

tive tissue cells must sustain peak mechanical stresses as high as 10–20 MPa (100–200 atm). These dynamic stresses produce fluid flows within the matrix that can affect intratissue solute transport and the concentration of solute species at the boundaries of tissues *in vivo* (O'Hare *et al.*, 1990). Such effects must therefore be taken into account in tissue-engineering design *in vitro*.

Given these diverse tissue types and geometric constructs, mathematical modeling of transport processes can be critically important in the design of tissue reactors, the basic understanding of the spatial and temporal distribution of small and large solutes in newly developing tissues, and the understanding of failure modes that might result from inadequate transport. We briefly summarize next the governing transport laws for solutes within tissues and the boundary conditions at the tissue/media interface. These general laws may then be adapted to the particular cell and tissue types of interest.

First, the one-dimensional flux  $N_i$  of the  $i$ th species within the tissue due to diffusion, convection, and electrical migration (ohmic conduction) is described by the flux equation:

$$N_i = \phi \left( -D_i \frac{\partial c_i}{\partial x} + \frac{z_i}{|z_i|} \mu_i c_i E \right) + W_i c_i U \quad (18.5)$$

where  $c_i$  is the solute concentration at the position  $x$ ,  $\phi$  is the matrix (tissue) porosity,  $z_i$  is the valence of the solute (if charged),  $U$  is the fluid velocity relative to the matrix (averaged over the total matrix area), and  $E$  is the electric field within the matrix (e.g., induced by diffusion of ionic species or by electrokinetic effects, such as flow-induced streaming potentials through a charged matrix). The intrinsic transport parameters  $D_i$ ,  $\mu_i$ , and  $W_i$  represent, respectively, the intratissue diffusivity of the solute, the electrical mobility, and a hindrance factor for convection that incorporates hydrodynamic and steric interactions between solute molecules and the matrix molecules forming the pore walls. Even in the absence of net fluid convection, frictional hydrodynamic and steric interactions between solute, matrix, and solvent can play a critical role in transport and may cause significant differences between the intratissue values of  $D_i$ ,  $\mu_i$ , and their corresponding values in free solution (Deen, 1987). In general, the flux Eq. (18.5) is general, in that it applies to ionic solutes in the medium, small neutral and charged solutes (e.g., amino acids, glucose), and large neutral and charged macromolecular solutes. For small solutes,  $W \rightarrow 1$ , and the values of  $D_i$  and  $\mu_i$  may be close to their free solution values; for larger solutes,  $W < 1$ , and  $D_i$  and  $\mu_i$  as written in Eq. (18.5) implicitly incorporate associated hindrance factors (Deen, 1987).

It is therefore necessary to measure or estimate values for the intrinsic transport parameters  $D_i$ ,  $\mu_i$ , and  $W_i$  in order to predict solute distribution profiles within the tissue construct. To predict the spatial and temporal distribution of

**FIG. 18.2.** The flux of macromolecular and small solutes within a cell-seeded matrix results from diffusion, convection (fluid velocity  $U$ ), and electrical migration if the solute is charged; an electric field  $E$  exists within the tissue (caused by fluid flow or by ion concentration gradients).

solutes in the neotissue, the flux equation is incorporated into the continuity law:

$$\frac{\partial c_i}{\partial t} = \frac{\partial N_i}{\partial x} + \sum_i (G_i - R_i) \quad (18.6)$$

where  $G_i$  and  $R_i$  represent chemical reaction rates associated with binding of solutes to cells or matrix molecules. In the absence of binding, electric migration, and convection effects, the continuity law, Eq. (18.6), reduces to Fick's second law for molecular diffusion. For the case of purely diffusive nutrient transport within a matrix containing cells acting as point sinks, the continuity law, Eq. (18.6), would reduce to the diffusion/reaction Eq. (18.1).

Electroneutrality within the tissue, including charges on all solute molecules ( $i$ ) and matrix molecules ( $m$ ), requires that

$$z_m c_m + \sum_i (z_i c_i) = 0 \quad (18.7)$$

Although tissues may have a high water content, the concentration of solutes within tissue water may be very different from that in the bathing medium because of size and charge effects. In general, the solute partition coefficient  $\kappa$  is defined as the ratio of the solute concentration within the tissue fluid to that in the bathing medium,  $\kappa = c^{\text{tiss}}/c^{\text{med}}$ . This partition coefficient acts as a boundary condition for the flux and continuity equations, which are written specifically in terms of solute concentrations inside the tissue. In addition, for charged solutes in the presence of a charged matrix, this partitioning is further modified due to Donnan equilibrium considerations for positively and negatively charged species, giving the Donnan partition boundary conditions (Maroudas, 1979):

$$(c_{i+}^{\text{med}}/c_{i+}^{\text{tiss}})^{1/|z_i|} = (c_{j-}^{\text{tiss}}/c_{j-}^{\text{med}})^{1/|z_j|} \quad (18.8)$$

Finally, it is useful to recast the continuity law in terms of the dimensionless Peclet number,  $Pe$ , which is defined as the ratio of solute convection plus migration fluxes to the diffusive flux (Grimshaw *et al.*, 1989):

$$\frac{\partial c_i}{\partial t} = D_i \left[ \frac{\partial^2 c_i}{\partial x^2} + \frac{Pe}{X} \left( \frac{\partial c_i}{\partial x} \right) \right] \quad (18.9)$$

$$Pe = X \left( \frac{W_i U + \phi \mu_i E}{\phi D_i} \right) \quad (18.10)$$

where  $X$  is the characteristic tissue thickness over which transport must occur. Thus, Eq. (18.9) takes the form of a modified Pick's second law and puts into perspective the relative importance of the convective and electrical migration terms, given values for  $X$ ,  $D_i$ ,  $W_i$ , and  $\mu_i$ . It is apparent that for solutes having small enough  $D_i$  and/or large enough fluid flow, convection may have a significant effect in determining the solute distribution within the tissue. Said another way, convection and intratissue electrokinetic (e.g., electrophoretic) effects could significantly augment the transport

of nutrients and macromolecules, as compared to diffusion alone, over tissue dimensions  $X$ .

### Cell Migration

Polymeric scaffolds are often introduced, into which it is hoped that certain cell types will migrate while others do not. For instance, regeneration of bone tissue for enhanced healing of full-thickness injuries requires that osteoprogenitor cells from surrounding tissue colonize an implanted scaffold and that endothelial cells migrate in, to achieve neovascularization, whereas connective tissue fibroblast influx is undesirable. There are two approaches for controlling migration: (1) surface chemistry of the implanted material for selective cell adhesion interactions with the surface, influencing migratory behavior in a differential manner among various cell types, and (2) release of chemotactic attractants from within the implanted material to induce enhanced migratory responses of particular cell types.

The rate of cell population movement into a tissue can be quantified using a cell transport flux expression analogous to that for molecular diffusion and convection (Tranquillo *et al.*, 1988):

$$J_{\text{cells}} = -\mu \frac{\partial N}{\partial x} + \chi \left( \frac{\partial A}{\partial x} \right) N \quad (18.11)$$

where  $\mu$  is the cell random motility coefficient, analogous to a molecular diffusion coefficient, and  $\chi$  is the chemotaxis coefficient;  $\chi$  is a biphasic function of the attractant concentration,  $A$ , because chemotaxis arises from a spatial difference in the number of receptor/attractant complexes across a cell length. The first term in Eq. (18.11) represents cell dispersion down the spatial gradient of cell density, whereas the second term yields a directed, convective velocity for cell migration in the direction of an attractant concentration gradient. The values  $\mu$  and  $\chi$  can be measured in a variety of cell population assays, such as movement through a porous filter or under an agarose gel. They can alternatively be calculated from individual cell-tracking assays in which cell speed, directional persistence time, and directional orientation bias are determined, because the cell population parameters are related by theory to the individual cell parameters. Details on these approaches can be found elsewhere (Lauffenburger and Linderman, 1996).

A fair amount of effort has been devoted to quantitative understanding of how substrata properties of materials affect cell migration. A central concept that is beginning to show general verification is that the speed of migration depends in a biphasic manner on the strength of cell/substratum adhesiveness (see Fig. 18.3) (DiMilla *et al.*, 1991). This principle can account for a wide range of experimental observations of how migration speed varies with the density of extracellular matrix ligands immobilized on biomaterial surfaces, and for the effects of ligand affinity and competing soluble ligand (Palecek *et al.*, 1997; Wu *et al.*, 1994). This lack of monotonicity is unfortunate, of course, because it makes

**FIG. 18.3.** Qualitative representation of typical dependence of cell migration speed on the ratio of cell-substratum adhesion strength to cell-generated contractile force.

design of a material quite problematic; unless the full quantitative picture is well characterized, one may produce a substratum either too strongly adhesive or too weakly adhesive for effective cell locomotion. Additional modulating approaches may be possible, though, by means of other parameters influencing migration speed. For instance, the dependence illustrated in Fig. 18.3 actually entails the ratio of cell/substratum adhesiveness to effective cell contractile force, so on a given substratum migration can be enhanced or inhibited by factors altering cell force generation or the substratum compliance.

#### IV. CELL AND TISSUE MECHANICS

The mechanics of a tissue or tissue substrate plays a central role in many situations, ranging from the fabrication of cell-based vascular grafts to wound healing. The transmission of stresses between the extracellular matrix and the cell or between the cell membrane and its nucleus is an important factor in controlling the biological response of the cell to its environment. Even cell motility and adhesion are influenced by the elastic characteristics of the substrate on which they are grown. To appreciate these factors requires an understanding of mechanics, both at the microscale (e.g., a single protein and its interaction with an actin filament) and at the macroscale (e.g., the elastic properties of a cell-based tissue implant). Some of the basic concepts are outlined here, along with some examples of how these concepts are applied in the field of tissue engineering.

##### Elasticity

Before dealing with some of the complexities of real biologic materials, consider first the case of a simple uniform and isotropic elastic medium. The elasticity of a material is typically characterized by its stress-strain relationship, where the stress is the force acting per unit area and the strain is the fractional change in length of the specimen, both of which are tensorial quantities. In the case of uniaxial stress, a material might exhibit a stress-strain relation of the

**FIG. 18.4.** Plot of stress ( $\sigma$ ) vs. strain ( $\epsilon$ ), showing an initial linear region, in which the Young's modulus ( $E$ ) is constant, and a nonlinear region, with increasing  $E$ , leading ultimately to fracture of the specimen.

type shown in Fig. 18.4. In this instance, the relationship is linear (or nearly so) for small strains but becomes nonlinear as strains increase above a certain level. The elastic, or Young's, modulus ( $E$ ) is defined as the ratio of stress ( $\sigma$ ) to strain ( $\epsilon$ ); in this example,  $E$  would be constant for small strains, but eventually it would increase as the material experiences increasing strain.

The elastic modulus of most biologic tissues is highly nonlinear, exhibiting an increasing elastic modulus for higher strains. The fibrous elements that comprise the tissue matrix, however, are more likely to be linearly elastic over an appreciable range of strain. Elastin, for example, which can be stretched up to 300% of its initial length, has a nearly constant modulus. Table 18.1 shows the elastic moduli for several tissues and tissue components. Another important property of the material is the maximum amount of strain it can experience before it fractures, some values of which are also given in the table.

In contrast to elastic deformation, in which there exists a unique relation between the applied stress and material strain, in plastic deformation the material experiences an irreversible deformation, usually at high levels of stress, and fails to return to its original length when the stress is removed.

All the foregoing applies to uniaxial loading. If a material is isotropic, then its elasticity is the same, regardless of the direction in which it is tested, and its mechanical properties can be completely characterized by two parameters, e.g., its elastic modulus and Poisson ratio,  $\nu$ . Anisotropic materials, however, exhibit different stress-strain characteristics along the different coordinate directions. The wall of an artery, for example, is extremely stiff in the circumferential and axial directions but relatively compliant in the radial direction. The description of such materials can lead to considerable complexity, as evidenced by the fact that in a truly anisotropic material, 21 constants analogous to the Young's modulus are required to characterize completely a material's elasticity. Intermediate between these two extremes can

**Table 18.1.** Elastic constants for a variety of biologic materials<sup>a</sup>

<i>Material</i>	<i>Elastic modulus</i>	<i>Yield stress</i>	<i>Max. strain</i>	<i>Ref.</i>
Cortical bone	6–30 GPa	50–200 MPa	—	Cowin <i>et al.</i> (1987)
Collagen fibers	500 MPa	50 MPa	0.1	Kato <i>et al.</i> (1989)
Elastin	100 kPa	300 kPa	3.0	Mulcherjee <i>et al.</i> (1976)
Cartilage	10 MPa	8–20 MPa	0.7–1.2	Woo <i>et al.</i> (1987)
Skin	35 MPa	15 MPa	1.1	Yamada (1970)
Muscle fascia	340 MPa	15 MPa	1.17	Yamada (1970)
Tendon	700 MPa	60 MPa	0.10	Yamada (1970)

<sup>a</sup>Note that in many instances, the stress–strain relationship is highly nonlinear; the elastic moduli in those cases represent an approximate, characteristic value.

be found materials that are transversely isotropic, that is, materials that exhibit isotropic behavior in two dimensions but different properties in the third. Many biological materials (blood vessels, ocular sclera) can be well characterized as transversely isotropic because the primary force-supporting structures (collagen and elastin fibers) are oriented primarily in one plane.

The existence of contractile elements, such as smooth muscle cells in vessel walls or the myocardium or actomyosin filaments in the cytoskeleton, lends further complexity to material properties. As far as the elastic properties of the material are concerned, active constriction can be thought of as influencing both the elastic modulus of the material and the length of the sample under zero stress.

### Viscoelasticity and Pseudoelasticity

Although some materials (e.g., elastin, collagen) show an immediate elastic response such that they exhibit an immediate and constant deformation following the application of stress, tissues more often respond in a time-dependent fashion (Fig. 18.5). The initial elastic response of such materials is followed by a period of additional deformation, or creep, asymptotically approaching an equilibrium state at long times. Alternatively, when subjected to a periodic load, these materials display a degree of hysteresis when stress is plotted against strain. This is termed a *viscoelastic* response and is a result of several processes internal to the tissue. One is the transient movement of liquid through the tissue due to the nonuniform distribution of interstitial pressure that results from the application of stress. For example, if a disk of cartilage is subjected to a load as in Fig. 18.5, a gradient in fluid pressure is set up between the central regions and the edge of the specimen, which causes fluid to be expelled. The rate of deformation during this phase is clearly dependent on the permeability of the tissue.

Biological tissues are often referred to as *pseudoelastic* (Fung, 1981), in that, with periodic loading, they evolve to a stress–strain pattern that is repeatable from one cycle to the next and relatively insensitive to the strain rate. The resulting curve typically differs on extension from relaxation,

exhibiting some degree of hysteresis (Fig. 18.6). By treating the loading and unloading maneuvers separately, the viscoelastic characteristics of the material can be incorporated into an otherwise elastic description of the material.

It is often necessary to simulate the true viscoelastic response of a tissue specimen, as, for example, when subjected to an abrupt increase in load (Fig. 18.5). Several simple models have been devised for this purpose. Although these make no attempt to mimic the mechanism responsible for the viscoelasticity, they are useful descriptors that can be used to represent certain viscoelastic characteristics. The most common among these models are the Maxwell, Voigt, and Kelvin models. Each is composed of one or more springs and dashpots, as shown in Fig. 18.7. These simple models are sometimes used as a basis for constructing more complex descriptions of the material. For example, a continuum description has been used to study the mechanical characteristics of leukocytes (Schmid-Schönbein *et al.*, 1981), based on the Kelvin model of Fig. 18.7, by arranging them in various series and parallel networks. More recent models for the cytoskeleton take explicit account of the fibrous microstructure, treating it alternatively by a structure of interconnected beams undergoing deformation by bending (Satcher and Dewey, 1996), by an interconnected structure with some elements under tension and some under compression (Stamenovic *et al.*, 1996), or as a cross-linked network of long filaments exhibiting bending stiffness and experiencing thermal excitation (Storm *et al.*, 2005).

### Measurement of Mechanical Properties

A variety of methods have been employed to ascertain the mechanical characteristics of biological specimens, the method being determined by the elastic characteristics of the material, its size, and the particular property of interest.

For large-scale samples such as tissues and scaffolds used in tissue engineering, the simplest measurement that yields the elastic modulus of a specimen is the *uniaxial strain test*, in which the sample is grasped at two ends and pulled while axial strain and stress are simultaneously

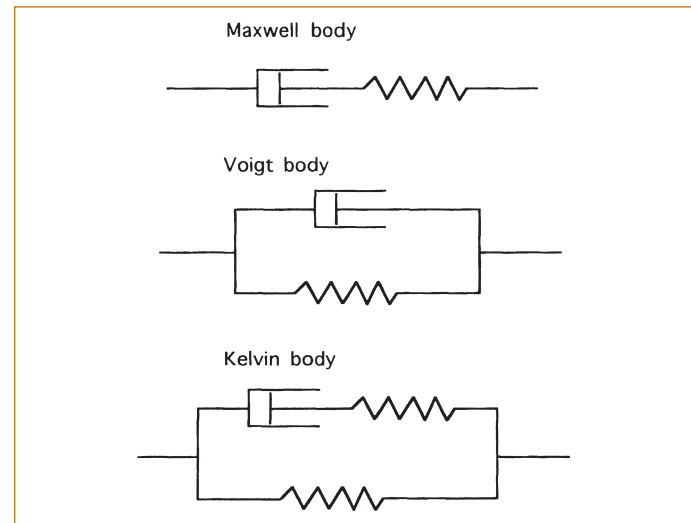

**FIG. 18.5.** (a) Stress ( $\sigma$ ; top) and strain ( $\epsilon$ ; bottom) plotted against time in a maneuver in which the stress is abruptly reduced. In a purely elastic material (dotted line), the strain immediately adjusts to a new level consistent with the new applied stress. A viscoelastic material (solid line) exhibits a further reduction in strain (creep), indicative of continued deformation following an initial elastic response. (b) The response of a cylindrical sample of cartilage subjected to a sudden compressive stress. The sample continues to compress with time as a result of water being expelled from the tissue through a porous platen. Reproduced with permission from Mow and Mak (1987).

**FIG. 18.6.** Pseudoelastic behavior of biological tissue. A stress–strain plot for a segment of a canine carotid artery undergoing cyclic loading; first and third cycles shown.  $T_1$  is the axial tension,  $\lambda_1$  is the axial stretch ratio, and  $L(t)/L_0$  with  $L_0$  is the relaxed length. The sample exhibits different curves for loading and unloading, which are highly reproducible. Reproduced with permission from Lee *et al.* (1967).

measured. In order to minimize end effects, the sample is often necked down to a lateral dimension in the central section, smaller than the ends, and the strain is measured directly in the necked region. Because stresses in both directions perpendicular to the axis of the specimen are zero, the elastic modulus is determined by the ratio of stress to strain,

**FIG. 18.7.** Three commonly used models for viscoelastic behavior composed of viscous elements (dashpots) and elastic elements (springs).

$E = \sigma_x / \epsilon_x$ . Poisson's ratio can be determined from the change of thickness of the specimen in the direction perpendicular to the applied stress. If the sample is anisotropic, additional uniaxial tests in the other two coordinate directions can be used. Alternatively, stresses can be applied in two (biaxial) or three (triaxial) dimensions simultaneously. These tests yield more information about the material, but they do so at the cost of greater complexity.

These tests are most often used to measure the properties of a material in tension. The compressive characteristics are also often of interest, especially in materials such as bone and cartilage, which are often subjected to compressive loads *in vivo*. For this purpose, specimens are generally cut into the shape of a short cylinder and compressed between two platens. In the case of cartilage, the platens may be permeable to allow water to escape as the sample is compressed, thereby obtaining information on the permeability of the sample from the time-dependent compression following the application of a load (Grodzinsky, 1983). Both confined and unconfined compression tests provide useful information. The advantage of confined compression, in which the sample is placed in a rigid cylindrical chamber, typically with nonpermeable side walls, is that the stress, strain, and flow of water are purely axial and the results can be more easily interpreted.

A third type of test measures the shear modulus, the stiffness of the sample to shear strain. Specimens are placed between two platens, one of which can be rotated. Shear strains with parallel flat platens vary as a function of radius, complicating the situation in nonlinear materials, so the upper platen is sometimes replaced by a cone with very shallow angle, in contact at the center of rotation (a cone-and-plate rheometer). This has the advantage that the entire sample is subjected to the same level of shear strain.

Any of the tests just mentioned are capable of measuring nonlinearities in the stress–strain behavior of a material, although the calculation of nonlinear properties is much easier with those methods that subject the sample to uniform strains. As mentioned earlier, biological materials typically become stiffer as the sample is stretched. Therefore, it is important to test the material with loads in the range of those the specimen is likely to experience *in vivo*. It is equally important to know the zero-stress state of a tissue, which, as has been demonstrated for a variety of vessels, is not necessarily achieved simply by reducing the transmural pressure to zero (Liu and Fung, 1988).

All these tests require excised specimens to be cut or machined into a particular shape. Often in the case of biological tissues, it is desirable to obtain measurements from the *in vivo* state so as to avoid the artifacts that are necessarily introduced by specimen removal. Although advantageous in many respects, *in vivo* testing also limits the choice of testing methods available. Fung and Liu (1995) argued for the importance of making measurements *in vivo*, and they have demonstrated how, in the case of a blood vessel, a battery of tests may be used to measure the mechanical properties of the arterial wall. Other methods — for example, the simple indentation of the material by a probe (Lai-Fook *et al.*, 1976) — can also be used.

Methods for testing the elastic and viscoelastic properties of cells and even individual molecules are rapidly becoming available. One approach for whole-cell measurements, micropipette aspiration, has been used in numerous

studies (e.g., Evans and Yeung, 1989; Guilak *et al.*, 2000) on various cell types. In this test, introduced over 20 years ago to study red blood cell mechanics and later for leukocytes, the cell is partially drawn into a micropipette by means of a negative pressure. Knowing the pressures acting and monitoring the extent of cell deformation by microscopy allow for estimation of cell elasticity. Cell poking, a method analogous to the indentation studies just discussed, can also be applied to individual cells (Zahalak *et al.*, 1990; Peeters *et al.*, 2003), as well as compression or extension between two surfaces (Caille *et al.*, 2002; Broers *et al.*, 2004).

In recent years, methods that probe the cell or cellular constituents on a smaller length scale have become more common, in part for their ability to measure subcellular structures, but also because they are less likely to interfere with normal biological function, leaving the cell in a more natural state. These methods might employ 1- to 5- $\mu\text{m}$ -diameter microparticles or an atomic force microscopy (AFM) probe. In AFM measurements, the probe is typically used to indent the cell locally, and the force displacement curve is used to infer the local modulus. This method has the capability of providing detailed maps of cell elasticity (Yamane *et al.*, 2000). Microparticle tracking methods can be either active or passive. In passive methods the thermal motion of either one or multiple particles is monitored to determine mean squared displacement over time, from which the shear modulus of the cell can be computed (Mason, 2000). Microparticles used for this purpose can either be membrane tethered or, if sufficiently small ( $\sim 1\ \mu\text{m}$  or less), internalized by the cell. Specificity for particular structures can be conferred by coating with specific ligands. Active methods use particles of similar size, but in conjunction with a magnetic trap (Glogauer and Ferrier, 1998) or optical tweezers (Block *et al.*, 1989; Kuo and Sheetz, 1993; Kuo, 1995) to actively oscillate or displace the particle and monitor particle displacements with high-speed video (Savin *et al.*, 2005), a quadrant detector (Yamada *et al.*, 2000), or laser interferometry (Pralle *et al.*, 1999). One advantage of all of these methods is their ability to provide measures of the complex shear modulus over decades in frequency (see e.g., Fabry *et al.*, 2001). Methods of analyzing the data assume the structures to be linearly viscoelastic, but that appears to be a reasonably good approximation for typical cell deformations. While any of these methods could, in principle, be applied to cells in a three-dimensional matrix, practical limitations either in introducing and attaching the microparticles or in observing their motion with sufficient resolution have proved difficult to overcome, although some success has recently been achieved (Panorchan *et al.*, 2006). Also of interest in tissue constructs is the level of force exerted by the cell on its surroundings. This can be done by imaging deformations of the matrix using, for example, either second harmonic imaging of collagen (Williams *et al.*, 2005) or displacements of microparticles embedded in the matrix (Dembo and Wang, 1999).

### I. INTRODUCTION

Control of the cellular environment is crucial for understanding the behavior of cells and for engineering cellular function (Jiang and Whitesides, 2003; Whitesides *et al.*, 2001; Xia and Whitesides, 1998). This chapter describes the use of a set of tools in microfabrication, called *soft lithography*, for patterning the substrate to which cells attach, the location and shape of the areas to which cells are confined, and the fluid environment surrounding the cells, all with micrometer precision. We summarize examples where these tools have helped to control the microenvironment of cells and have been useful in solving problems in fundamental cell biology. The methods described here are experimentally simple, inexpensive, and well suited for patterning biological materials.

How do tissues assemble *in vivo*? How do cells interact with each other in tissues? How do cells respond to stimuli? How do abnormal stimuli give rise to pathological conditions? Answering these fundamental biological questions and using the information thus obtained for medical applications requires understanding the behavior of cells in well-controlled microenvironments. Many of the challenges in

trying to control the environment experienced by individual cells lie in the relevant scales of size as well as the character of the stimuli. These scales of size range from angstroms (for molecular detail), through micrometers (for an individual cell), to millimeters and centimeters (for groups of cells); the types of stimuli that must be addressed include the molecular composition of the liquid in which the cell is immersed, the topographical and chemical composition of the surface to which the cells attach, the nature of neighboring cells, and the temperature.

Microfabrication and micropatterning using stamps or molds fabricated from elastomeric polymers (*soft lithography*) provide versatile methods for generating patterns of proteins and ligands on surfaces, microscale chambers for culturing cells, and laminar flows of media in capillaries, all in the size range of 0.1–100 micrometers (Gates *et al.*, 2005; Jiang and Whitesides, 2003; Whitesides *et al.*, 2001; Xia and Whitesides, 1998). Soft lithographic methods are relatively simple and inexpensive. The elastomeric polymer most often used in these procedures — polydimethylsiloxane (PDMS) — has several characteristics (optical transparency, ease of manipulation, and low cost) that make it attractive

for biological applications (McDonald and Whitesides, 2002). Although a new technology when compared to molecular biology, soft lithography is being increasingly used in cell biology, due to its biocompatibility, simplicity, and adaptability to biological and biochemical problems. This chapter gives an overview of the application of soft lithography to the patterning of cells and their fluidic environment, using micro-scale features and laminar flows.

Researchers have used a number of techniques to pattern cells and their environment (Letourneau, 1975). Before the 1990s, the most common was photolithography. This technique has been highly developed for the microelectronics industry; it has also been adapted, with varying degrees of success, for biological studies (Kleinfeld *et al.*, 1988; Letourneau, 1975; Ravenscroft *et al.*, 1998). Examples have included topographical features that confine the growth of snail neurons to silicon chips, as first demonstrations of interfacing natural computation with artificial ones (Merz and Fromherz, 2005; Zeck and Fromherz, 2001). As useful and powerful as photolithography is (it is capable of mass production at 70-nm resolution of multilevel, registered structures), it is not always the technique best suited for biological studies. It is an expensive and time-consuming technology; it is poorly suited for patterning nonplanar surfaces; it provides too little control over surface chemistry to pattern sufficiently diverse types of biomolecules on surfaces; it is poorly suited for patterning materials such as hydrogels; the equipment required to use it is rarely routinely accessible to biologists; and it is directly applicable to patterning only a limited set of photosensitive materials (e.g., photoresists).

## II. SOFT LITHOGRAPHY

Soft lithography solves many of the problems that required the application of microfabrication to biological problems (Chen *et al.*, 2005; Jiang and Whitesides, 2003; Whitesides *et al.*, 2001). Soft lithographic techniques are inexpensive, are relatively procedurally simple, are applicable to the complex and delicate molecules often dealt with in biochemistry and biology, can be used to pattern a variety of different materials, are applicable to both planar and curved substrates (Jackman *et al.*, 1995), and do not require stringent control (such as a clean-room environment) over the environment in which they are fabricated beyond that required for routine experiments with cultured cells (Whitesides *et al.*, 2001; Xia and Whitesides, 1998). Access to photolithographic technology is required only to create a master for casting the elastomeric stamps or membranes; even then, the requirement for chrome masks — the preparation of which is one of the slowest and most expensive steps in conventional photolithography — can often be bypassed in favor of high-resolution printing (Deng *et al.*, 2000; Linder *et al.*, 2003). Soft lithography offers special advantages for biological applications, in that the elastomer most often used (PDMS) is compatible with most types of

optical microscopy commonly used in cell biology, is permeable to gases such as O<sub>2</sub> and CO<sub>2</sub>, is mechanically flexible, seals conformally to a variety of surfaces (including most types of petri dishes), is generally biocompatible (Lee *et al.*, 2004), and can be implantable *in vivo*. The soft lithographic techniques that we discuss include microcontact printing, micromolding, patterning with microfluidic channels, and laminar flow patterning.

## III. SELF-ASSEMBLED MONOLAYERS (SAMs)

### Introduction to SAMs

Since many of the studies involving the patterning of proteins and cells using soft lithography have been carried out on self-assembled monolayers (SAMs) of alkanethiols on gold, we give a brief introduction to SAMs (Allara and Nuzzo, 1985; Bain and Whitesides, 1988; Jiang *et al.*, 2004b; Prime and Whitesides, 1991; Ulman, 1996). SAMs are organized organic monolayer films normally formed by exposing a surface of a gold film to a solution containing an alkanethiol (RSH). SAMs allow control at the molecular level by chemical synthesis of derivatized alkanethiol(s); this molecular control, in turn, gives control over the properties of the interface. The properties of surfaces covered with SAMs are often largely or entirely determined by the nature of the terminal groups of these alkanethiols. The ease of formation of SAMs and their ability to present a range of chemical functionality at their interface with aqueous solution make them particularly useful as model surfaces in studies involving biological components. Furthermore, SAMs can be easily patterned by simple methods such as microcontact printing ( $\mu$ CP) with features down to 100 nanometers in size (Love *et al.*, 2005; Xia and Whitesides, 1998). These features of SAMs make them structurally the best-defined substrates for use in patterning proteins and cells. SAMs on gold are used for many experiments requiring the patterning of proteins and cells, because they are biocompatible, easily handled, and chemically stable. SAMs on silver, although better defined structurally than those on gold, cannot be used in most experiments with cultured cells, due to the toxicity of silver (Ostuni *et al.*, 1999). SAMs on palladium and platinum are just starting to be explored (Jiang *et al.*, 2004a; Petrovykh *et al.*, 2006).

The substrates for SAMs are easy to prepare; once formed, SAMs are stable for weeks under conditions typical for culturing cells. Gold substrates are prepared on glass coverslips or silicon wafers by evaporating a thin layer of titanium or chromium (1–5 nm) to promote the adhesion of gold to the support, followed by a thin layer of gold (10–200 nm) (Lopez *et al.*, 1993). SAMs formed on these gold substrates are stable to the conditions used for cell culture, but care should be taken to avoid strong light and temperatures above ~70°C since both can result in degradation of the SAM (J. Huang and Hemminger, 1993; Love *et al.*, 2005).

### Preventing Protein Adsorption: “Inert Surfaces”

Proteins play an integral part in the adhesion of cells with surfaces: Cells require adsorbed proteins (or peptides that mimic parts of a protein) to adhere to the surface (Ruoslahti and Pierschbacher, 1987). Control of the interaction of proteins with a surface, therefore, enables the control of the interactions of cells with that surface. Most solid surfaces — especially hydrophobic surfaces — adsorb proteins. Thus, the main challenge in controlling the interactions of proteins and cells with surfaces lies in finding surfaces that *resist* nonspecific adsorption of proteins (surfaces that we call *inert*, for brevity). Inert surfaces provide the background necessary for spatially restricting protein adsorption or for preparing surfaces that bind only specific proteins and are used in patterning proteins and cells, as biomaterials (Andrade *et al.*, 1996; Han *et al.*, 1998), and in the construction of biosensors (Mrksich and Whitesides, 1995).

SAMs terminated in oligo(ethylene glycol) ( $\text{EG}_n$ ,  $n > 2$ ) resist the adsorption from solution of all known proteins and their mixtures (Prime and Whitesides, 1991, 1993; Whitesides *et al.*, 2001). We know that  $\text{EG}_n$  groups are not unique in their ability to make inert SAMs. For example, several polar functional groups that do not contain H-bond donors often make good components of inert surfaces (Chapman *et al.*, 2000; Kane *et al.*, 2003). The combination of inert and adsorptive surfaces with soft lithographic techniques enables the facile patterning of proteins and cells. Patterns of hydrophobic regions (for example, SAMs

terminated in methyl groups) and regions that are “inert” provide the basis for most work using patterned cells.

A number of other substances also make the surface more or less inert. Many of them are used in connection with soft lithography, for example, bovine serum albumin (BSA) and related proteins (Sweryda-Krawiec *et al.*, 2004), man-made polymeric materials (e.g., polyethyleneglycol, or PEG) (Jeon *et al.*, 1991), and dextran (Frazier *et al.*, 2000).

## IV. MICROCONTACT PRINTING AND MICROFEATURES USED IN CELL BIOLOGY

### Patterning Ligands, Proteins, and Cells Using Microcontact Printing on SAMs

Microcontact printing ( $\mu\text{CP}$ ) is a technique that uses topographic patterns on the surface of an elastomeric PDMS stamp to form patterns on the surfaces of various substrates (Fig. 19.1) (Xia and Whitesides, 1998). The stamp is first “inked” with a solution containing the patterning component, the solvent is allowed to evaporate under a stream of air, and the stamp is brought into conformal contact with the surface of the gold film for intervals ranging from a few seconds to minutes. The thiol transfers to the gold film in the regions of contacts. Other components used as ink for  $\mu\text{CP}$  include activated silanes that react with the  $\text{SiOH}$  groups ( $\text{RSiCl}_3$  or  $\text{RSi}(\text{OCH}_3)_3$ ) present on the surface of silicon (with a native film of  $\text{SiO}_2$ ) and various ligands (such

**FIG. 19.1.** Molding from a master, microcontact printing ( $\mu\text{CP}$ ), and patterning of proteins and cells. **(A)** A method for generating stamps (also applicable for channels and other molds) of PDMS for  $\mu\text{CP}$ . A PDMS stamp is prepared by pouring PDMS liquid prepolymer on a “master” (generally generated by photolithography), followed by curing the PDMS and removing it (as an elastomeric solid) from the master. **(B)** A typical procedure used for  $\mu\text{CP}$ . A solution containing the patterning component of interest (ink) is applied to this stamp and the solution allowed to dry. This inked stamp is placed on a substrate to allow the ink to transfer to the substrate. A substrate patterned with SAMs remains after removal of the stamp. **(C)** Selective adsorption of fibronectin onto a surface patterned by SAMs into areas that either promote or resist the adsorption of proteins, by  $\mu\text{CP}$ , visualized by immunostaining. **(D)** Patterned attachment and spreading of cells on the protein-patterned substrate in C.

as amine-containing compounds) that react with activated SAMs (usually resulting in the formation of a peptide bond that tethers ligands with surfaces) (Lahiri *et al.*, 1999; Yan *et al.*, 1998).

The most general and reliable method for patterning proteins is accomplished by preparing areas of SAMs that promote the adsorption of proteins, surrounded by regions that resist adsorption of proteins (regions that we call *inert background*), and allowing proteins to adsorb onto the adsorbing regions from solutions. For example, we used microcontact printing to pattern gold surfaces into regions terminated in methyl groups and then filled the rest of the surface of gold with an oligo(ethylene glycol)-terminated thiol to form inert regions (Lopez *et al.*, 1993). Immersion of the patterned SAMs in solutions of proteins such as fibronectin, fibrinogen, pyruvate kinase, streptavidin, and immunoglobulins resulted in adsorption of the proteins exclusively on the methyl-terminated regions (Lopez *et al.*, 1993). Characterization of patterns of adsorbed proteins with electron and optical microscopy shows that the layers of adsorbed protein appeared to be homogeneous. Alternatively, proteins can be anchored to ligands patterned onto surfaces by  $\mu$ CP; for example,  $\mu$ CP of biotin onto activated SAMs allows the biospecific immobilization of avidin on the surface (Lahiri *et al.*, 1999).

The ability of  $\mu$ CP to create patterns of ligands and proteins allows the patterning of many anchorage-dependent cells (most normal cells in multicellular organisms are anchorage dependent) (Alberts *et al.*, 2002); this patterning confines them to specific regions of a substrate and allows the precise control of the size and shape of the cells (Fig. 19.1). For example,  $\mu$ CP allows the partition of the surface of gold into regions presenting  $\text{EG}_n$  groups and methyl groups (Mrksich and Whitesides, 1996). After we coated the substrates with fibronectin, bovine capillary endothelial cells attached only to the methyl-terminated, fibronectin-coated regions of the patterned SAMs. The cells remained attached in the patterns defined by the underlying SAMs for five to seven days. We have also used SAMs on palladium for confinement of mammalian cells (Jiang *et al.*, 2004a). EG-terminated SAMs on palladium allow the patterning of individual cells, groups of cells, as well as focal adhesions (subcellular complexes that enable cell-substrate attachment, FA) for over four weeks; similar SAMs on gold confined cells to patterns for one to two weeks.

### Other Types of Microcontact Printing

It is possible to pattern certain proteins (ones that can withstand drying onto the surface of the stamp and stamping) directly onto surfaces (Bernard *et al.*, 1998, 2000, 2001; Mayer *et al.*, 2004; St. John *et al.*, 1998). Direct patterning of proteins, however, is typically applicable only to structurally stable proteins and is usually more demanding experimentally than patterning via SAMs (Kam and Boxer, 2001). The surface of the PDMS stamp used in this type of

procedure must be rendered hydrophilic by exposure to a plasma before use (Bernard *et al.*, 2000).

Patterning cells directly with  $\mu$ CP was thought to be unfeasible, because most cells are too delicate to be dried or stamped. Recently, however, we have demonstrated the stamping of proteins and cells directly with a soft hydrogel stamp (agarose) that contains large amounts of water (Mayer *et al.*, 2004; Stevens *et al.*, 2005). The resolution of this technique (tens of micrometers) is not comparable to  $\mu$ CP with PDMS and SAMs, but it makes patterning cells at this large size range easier than patterning with SAMs.

Other workers have used  $\mu$ CP for different types of cells on other types of surfaces. Craighead and coworkers patterned polylysine on surfaces of electrodes to confine the growth of neurons (James *et al.*, 2000). Zhang *et al.* have synthesized oligopeptides containing a cell-adhesion motif at the N-terminus connected by an oligo (alanine) linker to a cysteine residue at the C-terminus (Zhang *et al.*, 1999). The thiol group of cysteine allowed the oligopeptides to form monolayers on gold-coated surfaces. They used a combination of microcontact printing and these self-assembling oligopeptide monolayers to pattern gold surfaces into regions presenting cell-adhesion motifs and oligo(ethylene glycol) groups that resist protein adsorption. Wheeler *et al.* created patterns of covalently bound ligands and proteins on glass coverslips and used these patterns to control nerve cell growth (Branch *et al.*, 1998). In addition, polymers of EG and supported phospholipids have been used on a series of different substrates for patterning cells (Amirpour *et al.*, 2001; Kam and Boxer, 2001; Michel *et al.*, 2002; Tourovskaia *et al.*, 2003).

### Dynamic Control of Surfaces

It is possible to modulate the ability of surfaces to promote the adhesion of cells by controlling the composition of the surfaces. A relatively simple method to achieve this control is to desorb EG-terminated SAMs electrochemically from a substrate patterned with cells in a buffer containing proteins that promote attachment of cells (Jiang *et al.*, 2003). Electrochemical desorption converts inert areas into regions that can promote the adsorption of proteins and adhesion of cells, and thus it allows initially confined cells to move out of their patterns (Fig. 19.2). Mrksich and coworkers have used electrochemical conversion of a hydroquinone-terminated SAM into a quinone-terminated SAM to allow the attachment of a cyclopentadiene-tether peptide (which allows the immobilization of cells via the binding of integrin receptors on cell surface) to “turn on” an otherwise-inert SAM for adhesion of cells (Yousaf *et al.*, 2001a). Mrksich has used this technique for the patterning of multiple types of cells on surfaces (Yousaf *et al.*, 2001b). A newer technique from the same group involves first desorption of an immobilized ligand (patterned in certain areas on the surface) and detachment of cells adhered to the surface via this ligand, on application of an electrical reduction, and a subsequent electrical oxidation of the substrate for immobilizing another

**FIG. 19.2.** Using electrochemical desorption of EG-terminated SAMs to release confined BCE cells and allow their free movement. Initially, bovine capillary endothelial cells are confined to a patterned array of hydrophobic regions (SAMs terminated in methyl groups) and surrounded by regions that are “inert” (SAMs terminated in EG-terminated groups). Application of a cathodic voltage desorbs the EG-terminated SAMs to allow cells initially confined to move freely on the surface. The numbers indicate time after application of electrochemical treatment (in minutes).

ligand that allows the migration of adherent cells (that were initially confined to certain areas on the surface) (Yeo *et al.*, 2003). Some of the methods for preparing the appropriate thiols employed by Mrksich *et al.* may be too complicated for routine use in a regular cell biology laboratory, but the demonstration of such sophisticated control of the interactions between the cell and solid substrates is unprecedented. Another set of electrochemical methods can be used to activate BSA-rendered inert surfaces for cell adhesion (Kaji *et al.*, 2004, 2005).

There is a set of photochemical methods that allow the tuning of the inertness of SAMs. Mrksich and coworkers have devised a SAM that is initially inert but has in it a nitro-veratryloxycarbonyl-protected hydroquinone, which can be oxidized photochemically to generate a benzoquinone group, which, in turn, allows the attachment of a ligand for immobilization of cells on surfaces (Dillmore *et al.*, 2004). Another method for photoactivation of the surface utilized a photochemical process that desorbed a ligand from SAMs on surfaces. BSA, initially physically adsorbed on the surface via a photocleavable 2-nitrobenzyl group-terminated SAM, made this surface inert; photochemistry-mediated desorption of the 2-nitrobenzyl group, and therefore BSA, allowed cells to adhere to the surface (Nakanishi *et al.*, 2004). Both techniques allow the use of the mercury lamp on a fluorescent microscope of the kind typically used for experiments with cultured cells to carry out the required electrochemistry.

Takayama and his coworkers fabricated substrates that allow the dynamic control of focal adhesions (FAs). They first generated a slab of PDMS with a brittle surface by means of oxygen plasma treatment and then made the surface inert by means of physical adsorption of a polymer

containing moieties of PEG (Zhu *et al.*, 2005). By stretching the slab, they created cracks on the surface, which are not covered with the polymer-containing PEG; these cracks could thus promote the formation of FAs and adhesion of cells. Releasing the stress on the slab PDMS closed these cracks and again prevented the adhesion of cells. This stretch-and-release process could be recycled multiple times.

A number of other techniques also allow the patterning and dynamic patterning of proteins and cells in time and space. These techniques are related to soft lithography in one way or another (Co *et al.*, 2005; Kumar *et al.*, 2005; Ryan *et al.*, 2004).

### Patterning with Microtopographies

Microtopographies include membranes with microholes, microwells, microneedles, and grooves or steps on surfaces. It is possible to confine cells to micropatterns using either elastic membranes that carry holes or microwells (Folch *et al.*, 2000; Ostuni *et al.*, 2000, 2001). Some of these techniques also allowed the initial confinement, then release, of groups of cells (Folch *et al.*, 2000; Ostuni *et al.*, 2000).

Chen and his coworkers fabricated stamps with multiple levels that allowed the patterning of several different types of proteins and cells at once (Tien *et al.*, 2002). Chen *et al.* also used bowtie-shaped microwells of agarose gel both to confine individual cells to particular shapes and to allow cells to be close to each other without mutual contact (Nelson and Chen, 2002). Positioning cells next to each other while preventing their direct contact is difficult to achieve with  $\mu$ CP alone. They also fabricated arrays of micropillars (in sizes much smaller than a single cell) to

probe forces that cells apply to the substrate as they adhere to and migrate on solid surfaces (Tan *et al.*, 2003). Tien and coworkers succeeded in molding microstructures in hydrogels of resolution larger than 5 micrometers and used these structures to generate arrays of cells in three dimensions (Tang *et al.*, 2003).

We also studied the issue of topographical contact guidance — how cells interact with chemically homogeneous surfaces that have topographical features. These studies provide simple methods for further studies of this interesting and complex type of interactions (Jiang *et al.*, 2002; Lam *et al.*, 2006; Takayama *et al.*, 2001b).

### Fundamental Studies in Cell Biology Using Patterned Substrates

The ability to pattern proteins, groups of cells, single cells, and their FAs has led to new studies on the effect of patterned surface environments and cell shape on cell behavior.

Our first attempt in these studies was to prepare (via  $\mu$ CP) substrates consisting of square and rectangular islands of laminin surrounded by inert regions and to study the behavior of rat hepatocytes on them (Singhvi *et al.*, 1994). The cells conformed to the shape of the laminin patterns; the patterning allowed the control of cell shape independent of the density of ligands in the extracellular matrix (ECM). We observed that cell size, regardless of ECM ligand density, was the major determinant of cell growth and differentiation. We then used  $\mu$ CP to prepare substrates that presented circular cell-adhesive islands of various diameters and interisland spacings (Chen *et al.*, 1997; Dike *et al.*, 1999). Such patterns allowed the control of the extent of cell spreading without varying the total cell-matrix contact area. We found that the extent of spreading (the projected surface area of the cell), rather than the area of the adhesive contact, controlled whether the cell divided, remained in stationary phase, or entered apoptosis.

Dike *et al.* (1999) used  $\mu$ CP to prepare substrates with cell-adhesive lines of varying widths. They found that bovine capillary endothelial cells (BCE) cultured on 10- $\mu$ m-wide lines underwent differentiation to capillary tube-like structures containing a central lumen. Cells cultured on wider (30  $\mu$ m) lines formed cell-cell contacts, but these cells continued to proliferate and did not form tubes.

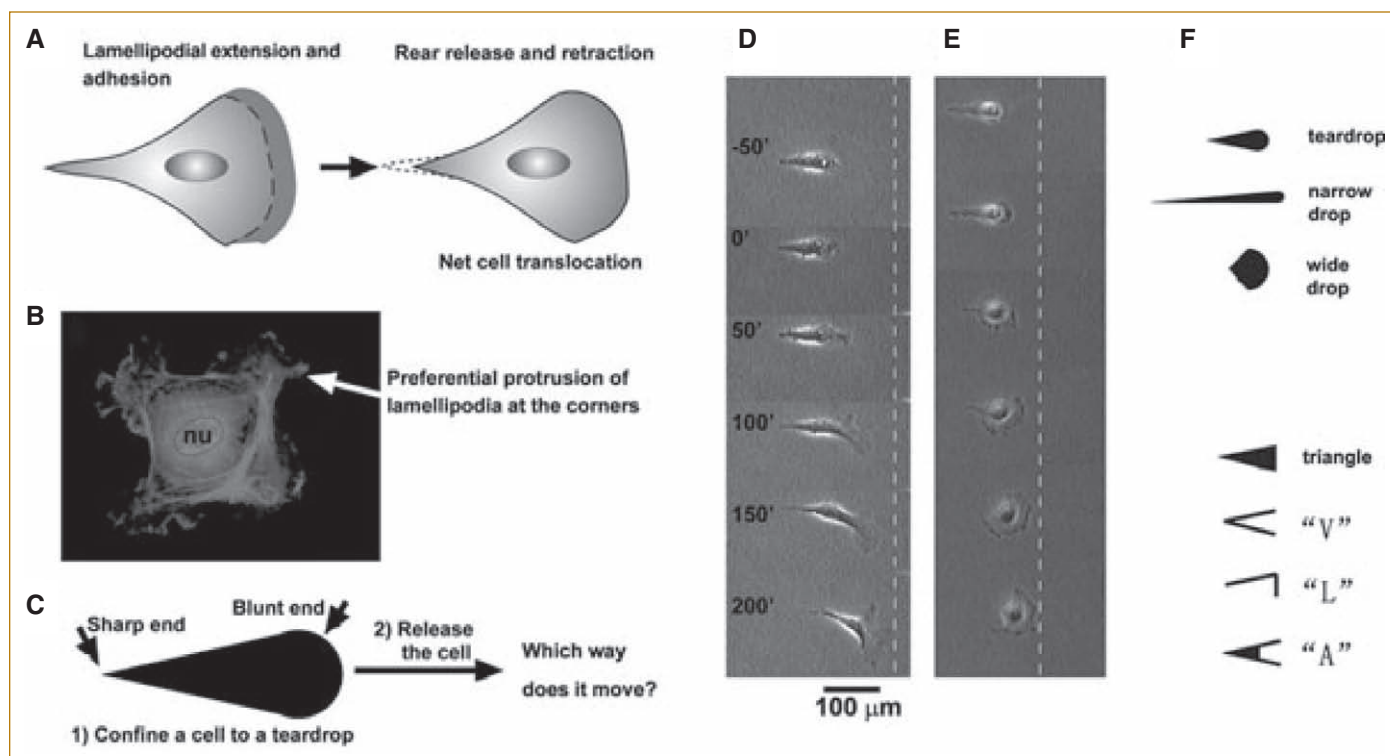

Recent progress in understanding how cell adhesion regulates cell physiology has used methods related to micropatterning. In several model types of cells, the strength of cell-substrate adhesion increased as the allowed area of cell adhesion increased, for small areas (typically less than 300  $\mu$ m<sup>2</sup>); but the strength of adhesion remained constant for larger areas (Gallant *et al.*, 2005; Tan *et al.*, 2003). These results related cell spreading and the strength of cell attachment empirically. Within the focal adhesion (FA), integrin receptors need to aggregate in order to activate the appropriate biochemical pathways for adhesion of cells

(Assoian and Zhu, 1997; Hotchin and Hall, 1995; Schwartz *et al.*, 1991). It has not been clear, however, at what maximum separation integrin receptors can still perform their normal functions. Bastmeyer has used different combinations of micropatterns to determine that cells could adhere to surfaces with arrays of circles with area of 0.1  $\mu$ m<sup>2</sup>, when the spacing between these circles is less than 5  $\mu$ m; but when the separation between these circles is larger than 30  $\mu$ m (and when the circles are larger than 1  $\mu$ m<sup>2</sup>), cells fail to adhere and spread on these surfaces (Lehnert *et al.*, 2004). This result gives a semiquantitative description of the geometrical requirements for clustered integrins.

Using a combination of self-assembly of nanoparticles and micropatterns, Spatz and colleagues definitively determined the maximum distances (73 nm) between individual integrin receptors in order for normal cell adhesion to occur (Arnold *et al.*, 2004). Another recent report shows that when FAs mature into larger-than-normal sizes, they appear to exert four times as much stress on the surface than normal FAs; this result might be important for myogenesis, the process of the formation of muscle fibers (Goffin *et al.*, 2006).

Micro-scale features enable the studies of the movement of mammalian cells. The extension of lamellipodia is an important process in the movement of cells. Bailly *et al.* (1998) used micropatterned substrates to study the regulation of lamellipodia during chemotactic responses of mammalian carcinoma cells to growth factors. On stimulation with epidermal growth factor, the cells extended their lamellipodia laterally out of their patterns of confinement, over the inert part of the substrate. This result showed that the extension of lamellipodia could occur independent of any contact with the substrate. Contact formation was, however, necessary for stabilizing the protrusion. We further observed that when endothelial cells were confined to patterns with corners (such as triangles and squares), their lamellipodia tended to spread most actively from the corners of these shapes (Brock *et al.*, 2003; Parker *et al.*, 2002).

Most moving mammalian cells adopt asymmetric shapes. We have examined whether the asymmetry in the shape of a cell is connected to the direction of its movement (Jiang *et al.*, 2005a) (Fig. 19.3A). Since moving cells often appear to have a teardrop shape, we confined cells to teardrop-shaped patterns and then used electrochemistry to allow free cell movement. It is tempting to assume that the released cells would move toward the sharp end of the teardrop pattern, considering that lamellipodia tend to extend from sharp corners; but a teardrop-shaped cell resembles a naturally moving cell (with the *blunt* end being the front) (Fig. 19.3). The conflicting observations left unclear the direction in which a teardrop-shaped cell would move once released. We released teardrop-shaped cells electrochemically and determined that these preshaped cells appear to prefer moving toward their blunt ends.

**FIG. 19.3.** Understanding the relationship between cell shape and the direction of cell migration. **(A)** A typical migrating cell has an asymmetric, teardrop-like shape and moves toward the blunt end. **(B)** When confined to shapes that have sharp corners, lamellipodia tend to extend out of the sharp corners. **(C)** A cell initially confined to a teardrop shape and then subsequently released may choose which way it moves: toward its blunt or sharp end. **(D)** **(E)** Individual 3T3 cells and COS cells, respectively, were initially confined to teardrop shapes and then released to move freely across the surface. The movement was predominantly toward the blunt end. Numbers indicate time after the application of electrochemical potential (minutes). **(F)** Different initial patterns used to confine cells.

To understand the issue in detail, we varied the initial shapes. It appeared that “narrow drops” (regardless of details of the shape) had a similar capability to direct cell migration, while “wide drops” failed to do so. Triangular patterns (having a similar aspect ratio to the teardrop) also direct cell migration, to the same extent as the teardrop, further confirming that the asymmetry of the initial shape alone could direct cell movement. In contrast, symmetric patterns such as rectangles, squares, and circles failed to direct cell migration. To determine whether it was the shape of the spread cell or the uneven distribution of FAs underneath the cell that was responsible for directed cell motion, we started cells on “L”-, “V”-, and “A”-shaped patterns. Because individual cells could span these patterns, the immobilized cells resembled each other in overall geometry, and their geometry was similar to that of cells confined to triangular patterns. But these patterns allowed different distributions of FAs. Triangles and “L”-shaped cells allowed more FAs in the blunt end, “V”-shaped patterns allowed the same amount of the FAs in the blunt end as in the sharp end, while “A”-shaped patterns allowed more FAs in the sharp end. All these patterns appeared to direct cell migration to the same extent, thus confirming that the overall shape of cells was the determining factor in directing cell motion.

Micron-scale tools based on soft lithography have also been used in studies of cell division. Even though most mammalian cells round up and almost completely detach from the substrate when they divide, Bornens’ group has used  $\mu$ CP to show that the shape of the ECM to which cells initially attach determines the direction of cell division (Thery *et al.*, 2005).

Micropatterns could also bias the differentiation of human mesenchymal stem cells: When allowed to adhere and spread, the stem cells became osteoblasts; when spreading was prohibited by small patterns of confinement, stem cells became adipocytes (McBeath *et al.*, 2004).

These tools offer opportunities to study not just single cells, but groups of cells. For example, Chen and coworkers devised experiments to control the size and the contact between a pair of two cells, thus definitively proving that cell–cell contact, not soluble factors alone, enable cell contact-mediated proliferation of cells in culture (Nelson and Chen, 2002). Toner and colleagues showed, by patterning of hepatocytes and nonparenchymal cells with precise geometrical parameters, that the interface between the two types of cells is critical for the function of hepatocytes (Bhatia *et al.*, 1999). Ingber and his coworkers discovered, using patterned groups of two or more endothelial cells, that

spontaneous ordering arises and patterns that resemble the Chinese Yin-Yang ideograph would emerge while endothelial cells migrate on the patterns (Brangwynne *et al.*, 2000; S. Huang *et al.*, 2005). Studying groups of tens to hundreds of cells patterned into defined geometries, Chen and coworkers realized that the shapes of sheets of cells influence the mechanical forces each cell within experiences, and these forces affect the physiology of individual cells differently, as a function of where in the sheets these cells are located (Nelson *et al.*, 2005).

## V. MICROFLUIDIC PATTERNING

The use of microfluidic channels allows patterning surfaces by restricting the flow of fluids to desired regions of a substrate. The patterning components — such as ligands, proteins, and cells — are deposited from the solution to create a pattern on the substrate.

Delamarche *et al.* used microfluidic patterning ( $\mu$ FP) to pattern immunoglobulins with submicron resolution on a variety of substrates including gold, glass, and polystyrene (Delamarche *et al.*, 1997). Only microliters of reagent were required to cover square millimeter-sized areas. Patel *et al.* (1998) developed a method to generate micron-scale patterns of any biotinylated ligand on the surface of a biodegradable polymer. These investigators prepared biotin-presenting polymer films and patterned the films by allowing solutions of avidin to flow over them through 50- $\mu$ m channels fabricated in PDMS. The avidin moieties bound to the biotin groups on the surface and served as a bridge between the biotinylated polymer and biotinylated ligands. Patterns created with biotinylated ligands containing the RGD or IKVAV oligopeptide sequences determined the adhesion and spreading of bovine aortic endothelial cells and PC12 nerve cells.

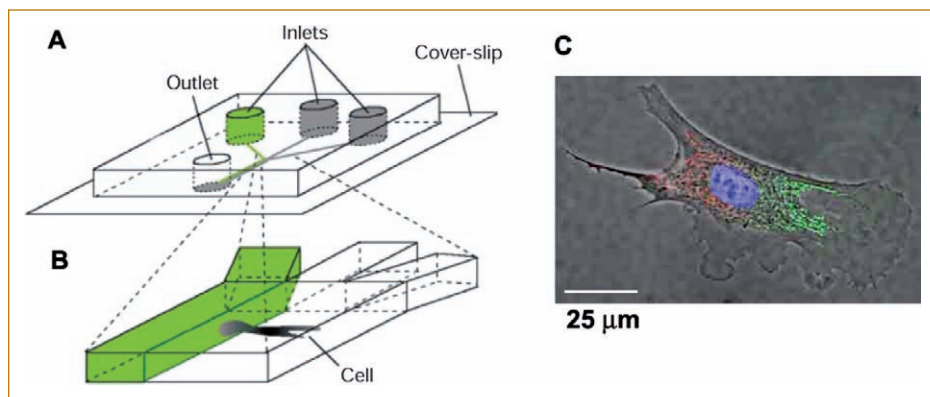

Both our group and Toner's group used  $\mu$ FP to produce patterns of adsorbed proteins and adherent cells on bio-compatible substrates (Chiu *et al.*, 2000; Folch *et al.*, 1999; Folch and Toner, 1998). We formed micropatterns of proteins deposited from fluids in separately addressable capillaries.

By allowing different cell suspensions to flow through different channels, we could pattern two types of cell on surfaces with high spatial precision. After the adhesion of two types of cells in different areas on the surface, we could remove the elastomeric stamps to allow the studies of the movement of two types of cells. By filling individual channels with different fluids, multiple components could be patterned at the same time without the need for multiple steps or the accompanying technical concerns of registration (although registration was required in the fabrication of the stamp itself).

## VI. LAMINAR FLOW PATTERNING

Laminar flow patterning (LFP) is a technique that can pattern surfaces and the positions of cells on them in useful ways (Takayama *et al.*, 2001b). It can also pattern fluids themselves (Takayama *et al.*, 1999). This technique utilizes a phenomenon that occurs in microfluidic systems as a result of their small dimensions — that is, low-Reynolds-number flow (Squires and Quake, 2005; Stroock and Whitesides, 2003). The Reynolds number ( $Re$ ) is a parameter describing the ratio of inertial to viscous forces in a particular flow configuration; it is a measure of the tendency of a flowing fluid to develop turbulence. The flow of aqueous fluids in capillaries usually has a low  $Re$  and is laminar. Laminar flow allows two or more streams of fluid to flow next to each other without any mixing other than by diffusion of their constituent molecules across the boundary between them (which is usually fairly slow). Diffusional motion of particulate components (e.g., cells) is even slower.

In a typical setup for LFP experiments, a network of capillaries is made by sealing a patterned PDMS slab with a glass slide or the surface of a petri dish (Fig. 19.4) (Takayama *et al.*, 1999). By passing streams of fluid with different compositions from the inlets, patterns of parallel stripes of flowing fluid are created in the main channel. It is possible, therefore, to treat different parts of a single cell with different reagents if a cell happens to span these stripes. Fig. 19.4

**FIG. 19.4.** Manipulation of two regions of a single bovine capillary endothelial cell using multiple laminar flows. **(A)** Experimental setup; **(B)** shows a close-up of the point at which the inlet channels combine into one main channel. **(C)** Fluorescence images of a single cell after treatment of its right pole with Mitotracker Green FM and its left pole with Mitotracker Red CM-H2XRos. The entire cell is treated with the DNA-binding dye Hoechst 33342.

illustrates the painting of a single cell with dyes that stained mitochondria located in different parts of the same cell (Takayama *et al.*, 2001a, 2003).

Using this technique, the positions and micro-environments of cells can be controlled simultaneously in several stripes in the same channel (Gu *et al.*, 2004; Sawano *et al.*, 2002). Using a similar approach, we could pattern the substrate with different proteins and cells (Takayama *et al.*, 1999). We can pattern the culture media over an individual cell by delivering chemicals selectively to cells. Since no physical barriers are required to separate the different liquid streams, different liquids can flow over different portions of a single cell.

Ismagilov and colleagues have used LFP to generate a step gradient in temperature to study the development of the embryos of the fruit fly *Drosophila melanogaster* (Lucchetta *et al.*, 2005). They treated the anterior (front) and posterior (back) of the embryo with media of different temperatures and observed that the fly embryos developed normally under such a condition. They concluded that in complex biochemical systems, there exist mechanisms for compensation. They further showed that if they reverse the temperature gradient within a certain time, embryos failed to develop normally. This observation shows there is a limitation of time for the mechanisms for compensation.

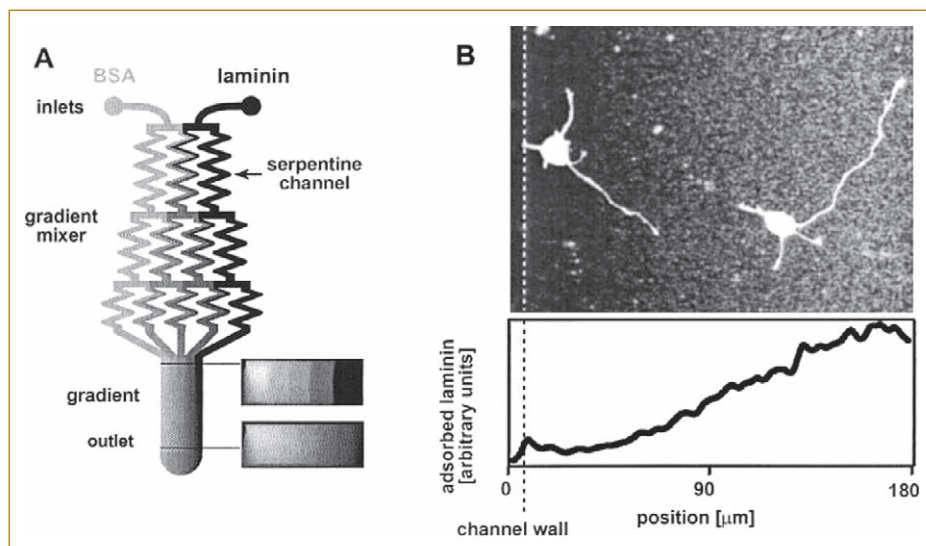

Another type of LFP generates gradients with parallel streams of flow of increasing or decreasing concentrations. We have generated gradients of biomolecules both in solution and on surfaces (Fig. 19.5) (Dertinger *et al.*, 2001; Jeon *et al.*, 2000). Because we can control the input concentration and the width of the microfluidic channel, it is possible to generate gradients of virtually any characteristics (e.g., the length and the slope), both in solution and on surfaces. We studied the generation of neuronal

polarity—the process of the selective formation of one axon and several dendrites from a number of initially equivalent neurites projecting from a single neuron—and found that a surface gradient of laminin was sufficient to guide the orientation of this process (Fig. 19.5) (Dertinger *et al.*, 2002). We further quantified the slope of the gradient and determined the minimum slope of the gradient required for this process to take place. We have also studied the chemotaxis of neutrophils in a solution of gradient of interleukin-8 (IL8) (Jeon *et al.*, 2002). The neutrophils migrate directionally toward increasing concentrations of IL8 in linear gradients. Neutrophils halt abruptly when encountering a sudden drop in the chemoattractant concentration (from maximum directly to zero). When neutrophils encounter a gradual increase and decrease in chemoattractant (from maximum gradually to zero), however, the cells initially cross the crest of maximum concentration but then head back toward the maximum. It would be very difficult to carry out experiments to answer questions of these types—questions covering the response of cells to the details of gradients over scales of microns—without the ability to form precisely controlled gradients.

LFP has some features that make it complementary to other patterning techniques used for biological applications. It takes advantage of easily generated multiphase laminar flows to pattern fluids and to deliver components for patterning. The ability to pattern the growth medium itself is a special feature that cannot be achieved by other processes. This method can pattern even delicate structures, such as portions of a mammalian cell. This type of patterning is difficult by other techniques. LFP can also give simultaneous control over the surface patterns, cell positioning, and the fluid environment in the same channel.

One may ask if the fluid flow required in the generation of laminar flows would cause problems for certain

**FIG. 19.5.** Generation of gradients using microfluidic networks, and use of these gradients to study neuronal differentiation. **(A)** In appropriately designed microfluidic channels, flows generate gradients of BSA and laminin in solution. **(B)** The gradient in solution became a gradient on the surface when proteins adsorb; and when rat hippocampal neurons grow on the gradient, the neurons extend their longest process (the presumed axon) toward the higher concentrations of laminin in the gradient of proteins on the surface.

experiments, such as the measurement of chemotaxis. Wikswo and coworkers addressed this issue by measuring the motility of HL60 leukemia cells (which express CXCR2 receptors) in a gradient of CXCL8 (Walker *et al.*, 2005). They found that high rates of flow can affect the motility of cells. Reasonably low rates of flow, however, do not affect measurements on motile cells.

A few recent examples have combined patterned substrates with patterned flows. We have fabricated gradients of proteins on surfaces in microchannels whose floors carry patterns generated by  $\mu$ CP (Jiang *et al.*, 2005b). Jeon and his coworkers have combined substrates patterned in topography and patterned flows to form a model system that conveniently isolates axons of rat hippocampal neurons from the rest of the cell for studies of their molecular biology (Taylor *et al.*, 2005). Langer and coworkers have fabricated microchannels that have micropatterns within them to immobilize proteins and cells (Khademhosseini *et al.*, 2004). Folch and coworkers have used micropatterns to form myotubes from myoblasts and then used laminar flows to deliver agrin, a proteoglycan found in the neuromuscular junction, precisely to these myotubes. In these experiments, he monitored the clustering of acetylcholine receptor (AChR), and his results corroborated the hypothesis that focalized release of agrin causes the clustering the AChR (Tourovskaia *et al.*, 2006).

## VII. CONCLUSION AND FUTURE PROSPECTS

Soft lithography brings to microfabrication low cost, simple procedures, rapid prototyping of custom-designed devices, three-dimensional capability, easy integration with existing instruments such as optical microscopy, molecular level control of surfaces, and biocompatibility (Jiang and Whitesides, 2003; Whitesides *et al.*, 2001). These techniques allow patterning of cells and their environments with convenience and flexibility at dimensions smaller than micrometers. We have described several complementary soft lithographic techniques — microcontact printing, patterning with microtopography, patterning using fluids in microfluidic channels, and laminar flow patterning — that are useful in their ability to pattern the microenvironment of cultured cells.

Microcontact printing is perhaps the simplest method for patterning surfaces. It also provides the highest resolution in patterns with the greatest flexibility in the shape and size of the patterns generated. It provides the best control when one needs to pattern only two types of ligands or proteins. Microtopographies can be useful for certain experiments where micropatterning alone is not sufficient. Microfluidic channels are well suited for patterning surfaces using delicate objects such as proteins and cells. They are also useful when multiple ligands, proteins, or cells need to be patterned. Laminar flow patterning is similar to pattern-

ing with individual microfluidic channels, except the individual flows are kept from mixing with each other by laminar flow, not by physical walls. The ability to pattern the fluid environment is the distinguishing feature of this method, and it enables laminar flow to be used to pattern the distribution of different fluids over the surface of a single mammalian cell. This capability allows patterning of portions of a single cell and remodeling of the cell culture environment, both in the presence of living cells. The combination of two or more of these techniques is starting to become useful for more sophisticated experiments.

Soft lithography is still practiced by a relatively small number of biologists, but its use is growing rapidly. There are many cell culture environments and related technologies that we have not discussed in this chapter; many of them relate to soft lithographic methods. For example, there are a number of methods of manipulation of chemistry on SAMs and tools of micropatterns to allow for molecular level control at the cell–substrate interface (Chapman *et al.*, 2000; Kandere-Grzybowska *et al.*, 2005; Kato and Mrksich, 2004).

Although we are starting to have more techniques for fabrication in three dimensions, patterning of cells in three dimensions is still difficult (Gates *et al.*, 2004, 2005; Shin *et al.*, 2004). We are making rapid progress, however, in the fourth dimension, i.e., time. Since we can turn the surface on and off for adhesion of cells and change the media at will in laminar flows, real-time monitoring of temporal changes in individual cells is possible (Jiang *et al.*, 2003; Takayama *et al.*, 1999; Yousaf *et al.*, 2001a). The optical transparency of PDMS makes it straightforward to pattern the intensity of light in cell cultures (Whitesides *et al.*, 2001). The gas permeability of PDMS may be useful in patterning the gas surrounding cells. PDMS is electrically insulating, and molding or fabricating electrically conducting wires in it should allow patterning of electric fields around cells (Kenis *et al.*, 1999; Takayama *et al.*, 1999). Gravitational fields can also be affected: Microfluidic culture chambers with adherent cells can be turned upside down without loss of the culture media. Temperature, fluid shear, and other factors may also be accurately patterned.

The functional potential of a cell is determined by its genetics. Realization of that potential depends, *inter alia*, on whether the cell is exposed to the appropriate environment for expression of particular sets of genes. Soft lithography provides tools for patterning cells and their environment with precise spatial control. This capability aids efforts to understand fundamental cell biology and advances our ability to engineer cells and tissues. The ease with which electronic components or other “nonbiological” components can be fabricated with soft lithography also paves the way for the engineering of cells and tissues for use in biosensors and hybrid systems (e.g., interfaces between semiconductor-based computation and biological computation) that combine living and nonliving components.

### I. INTRODUCTION

Scaffolds composed of synthetic and natural polymers have been essential components of tissue engineering since its inception (Vacanti, 1988). Polymers are currently used in a wide range of biomedical applications, including applications in which the polymer remains in intimate contact with cells and tissues for prolonged periods (Table 20.1). Many of these polymer materials have been tested for tissue-engineering applications as well. To select appropriate polymers for tissue engineering, it is helpful to understand the influence of these polymeric materials on viability, growth, and function of attached or adjacent cells. In addition, it is now possible to synthesize polymers that interact in predictable ways with cells and tissues; understanding the nature of interactions between cells and polymers provides the foundation to this approach.

This chapter reviews previous work on the interactions of tissue-derived cells with polymers, particularly the types of synthetic polymers that have been employed as biomaterials. The focus of the chapter is on interactions of cells with polymers that might be used in tissue engineering; therefore, both *in vitro* and *in vivo* methods for measuring cell-polymer interactions are described. The interactions of cells in flowing blood, particularly platelets, with synthetic polymer surfaces are also an important aspect of biomaterials design, but they are not considered here.

### II. METHODS FOR CHARACTERIZING CELL INTERACTIONS WITH POLYMERS

#### *In Vitro* Cell Culture Methods

Cell interactions with polymers are often studied *in vitro*, using cell culture techniques. While *in vitro* studies do not reproduce the wide range of cellular responses observed after implantation of materials, the culture environment provides a level of control and quantification that cannot be obtained *in vivo*. Cells in culture are generally plated over a polymer surface, and interaction is allowed to proceed for several hours; the extent of cell adhesion and spreading on the surface is then measured. By maintaining the culture for longer periods, perhaps for many days, the influence of the substrate on cell viability, function, and motility can also be determined. Since investigators use different techniques to assess cell interactions with polymers and the differences between techniques are critically important for interpretation of interactions, some of the most frequently used *in vitro* methods are reviewed in this section.

To perform any measurement of cell interaction with a polymer substrate, the polymeric material and the cells must come into contact. Preferably, the experimenter should control (or at least understand) the nature of the contact; this is a critical, and often overlooked, aspect of all of these measurements. Some materials are easily

**Table 20.1.** Some of the polymers that might be useful in tissue engineering, based on past use in biomedical devices

<i>Polymer</i>	<i>Medical applications</i>
Polydimethylsiloxane, silicone elastomers (PDMS)	Breast, penile, and testicular prostheses Catheters Drug delivery devices Heart valves Hydrocephalus shunts Membrane oxygenators
Polyurethanes (PEU)	Artificial hearts and ventricular assist devices Catheters Pacemaker leads
Poly(tetrafluoroethylene) (PTFE)	Heart valves Vascular grafts Facial prostheses Hydrocephalus shunts Membrane oxygenators Catheters
Polyethylene (PE)	Sutures Hip prostheses Catheters
Polysulphone (PSu)	Heart valves Penile prostheses
Poly(ethylene terephthalate) (PET)	Vascular grafts Surgical grafts and sutures
Poly(methyl methacrylate) (pMMA)	Fracture fixation Intraocular lenses Dentures
Poly(2-hydroxyethylmethacrylate) (pHEMA)	Contact lenses Catheters
Polyacrylonitrile (PAN)	Dialysis membranes
Polyamides	Dialysis membranes Sutures
Polypropylene (PP)	Plasmapheresis membranes Sutures
Poly(vinyl chloride) (PVC)	Plasmapheresis membranes Blood bags
Poly(ethylene-co-vinyl acetate)	Drug delivery devices
Poly(L-lactic acid), Poly(glycolic acid), and Poly(lactide-co-glycolide) (PLA, PGA, and PLGA)	Drug delivery devices Sutures
Polystyrene (PS)	Tissue culture flasks
Poly(vinyl pyrrolidone) (PVP)	Blood substitutes

fabricated in a format suitable for study; polystyrene films, for example, are transparent, durable, and strong. Other materials must be coated onto a rigid substrate (such as a glass coverslip) prior to study. But since cell function is sensitive to chemical, morphological, and mechanical properties of the surface, almost every aspect of material preparation

can introduce variables that are known to influence cell interactions.

### Adhesion and Spreading

Most tissue-derived cells require attachment to a solid surface for viability and growth. For this reason, the initial

events that occur when a cell approaches a surface are of fundamental interest. In tissue engineering, cell adhesion to a surface is critical because adhesion precedes other cell behaviors, such as cell spreading, cell migration, and, often, differentiated cell function.

A number of different techniques for quantifying the extent and strength of cell adhesion have been developed. In fact, so many different techniques are used that it is usually difficult to compare studies performed by different investigators. This situation is further complicated by the fact that cell adhesion depends on a large number of experimental parameters (Lauffenburger and Linderman, 1993), many of which are difficult to control. The simplest methods for quantifying the extent of cell adhesion to a surface involve three steps: (1) suspension of cells over a surface, (2) incubation of the sedimented cells in culture medium for some period of time, and (3) detachment of loosely adherent cells under controlled conditions. The extent of cell adhesion, which is a function of the conditions of the experiment, is determined by quantifying either the number of cells that remain associated with the surface (the adherent cells) or the number of cells that were extracted with the washes. Radiolabeled or fluorescently labeled cells can be used to permit measurement of the number of attached cells. Alternatively, the number of attached cells can be determined by direct visualization, by measurement of concentration of an intracellular enzyme, or by binding of a dye to an intracellular component such as DNA. In many cases, the adherent cells are further categorized based on morphological differences (e.g., extent of spreading, formation of actin filament bundles, presence of focal contacts). This technique is simple, rapid, and, since it requires simple equipment, common. Unfortunately, it is often difficult to control the force that is provided to dislodge the nonadherent cells, making it difficult to compare results obtained from different laboratories, even when they are using the same technique.

This disadvantage can be overcome by using a centrifuge or a flowing fluid to provide a reproducible detachment force. In centrifugal detachment assays, the technique just described is modified slightly: Following the incubation period, the plate is inverted and subjected to a controlled detachment force by centrifugation (McClay *et al.*, 1981). In most flow chambers, the fluid is forced between two parallel plates (Lawrence *et al.*, 1987). Prior to applying the flow field, a cell suspension is injected into the chamber, and the cells are permitted to settle onto the surface of interest and adhere. After some period of incubation, flow is initiated between the plates. These chambers can be used to measure the kinetics of cell attachment, detachment, and rolling on surfaces under conditions of flow. Usually, the overall flow rate is adjusted so that the flow is laminar, and the shear stresses at the wall approximate those found in the circulatory system; however, these chambers can be used to characterize cell detachment under a wide range of conditions.

Radial-flow detachment chambers have also been used to measure forces of cell detachment (Cozens-Roberts *et al.*, 1990). Because of the geometry of the radial-flow chamber, where cells are attached uniformly to a circular plate and fluid is circulated from the center to the periphery of the chamber along radial paths, the fluid shear force experienced by the attached cells decreases with radial position from the center to the periphery. Therefore, in a single experiment, the influence of a range of forces on cell adhesion can be determined. A spinning disc apparatus can be used in a similar fashion (F. Lee *et al.*, 2004). Finally, micropipette techniques can be used to measure cell membrane deformability or forces of cell–cell or cell–surface adhesion (Qin *et al.*, 2005).

### Migration

The migration of individual cells within a tissue is a critical element in the formation of the architecture of organs and organisms (Trinkhaus, 1984). Similarly, cell migration is likely to be an important phenomenon in tissue engineering, since the ability of cells to move, either in association with the surface of a material or through an ensemble of other cells, will be an essential part of new tissue formation or regeneration. Cell migration is also difficult to measure, particularly in complex environments. Fortunately, a number of useful techniques for quantifying cell migration in certain situations have been developed. As in cell adhesion, however, no technique has gained general acceptance, so it is difficult to correlate results obtained by different techniques or different investigators.

Experimental methods for characterizing cell motility can be divided into two general categories. In *visual assays*, the movements of a small number of cells (usually ~100) are observed individually (Tan, 2001). *Population techniques*, on the other hand, allow the observation of the collective movements of groups of cells: In filter chamber assays the number of cells migrating through a membrane or filter is measured (Boyden, 1962), while in under-agarose assays the leading front of cell movement on a surface under a block of agarose is monitored (Nelson *et al.*, 1975). Both visual and population assays can be quantitatively analyzed, enabling the estimation of intrinsic cell motility parameters, such as the random motility coefficient and the persistence time (see review in Saltzman, 2004).

### Aggregation

Cell aggregates are important tools in the study of tissue development, permitting correlation of cell–cell interactions with cell differentiation, viability, and migration as well as subsequent tissue formation. The aggregate morphology permits reestablishment of cell–cell contacts normally present in tissues; therefore, cell function and survival are often enhanced in aggregate culture. Because of this, cell aggregates may also be useful in tissue engineering, enhanc-

ing the function of cell-based hybrid artificial organs or reconstituted tissue transplants (Mahoney and Saltzman, 2001).

Gentle rotational stirring of suspensions of dispersed cells is the most common method for making cell aggregates (Moscona, 1961). While this method is suitable for aggregation of many cells, serum or serum proteins must be added to promote cell aggregation in many cases, thus making it difficult to characterize the aggregation process and to control the size and composition of the aggregate. Specialized techniques can be used to produce aggregates in certain cases, principally by controlling cell detachment from a solid substratum. For example, stationary culture of hepatocytes above a nonadherent surface (Parsons-Wingerter and Saltzman, 1993) or attached to a temperature-sensitive polymer substratum (Takezawa *et al.*, 1993) have been used to form aggregates. Synthetic polymers produced by linking cell-binding peptides (such as RGD and YIGSR) to both ends of poly(ethylene glycol) (PEG) have been used to promote aggregation of cells in suspension (Dai, 1994).

The kinetics and extent of aggregation can be measured by a variety of techniques. Often, direct visualization of aggregate size is used to determine the extent of aggregation, following the pioneering work of Moscona (1961). The kinetics of aggregation can be monitored in this manner as well, by measuring aggregate size distributions over time. This procedure is facilitated by the use of computer image analysis techniques or electronic particle counters, where sometimes the disappearance of single cells (instead of the growth of aggregates) is followed. Specialized aggregometers have been constructed to provide reproducible and rapid measurements of the rate of aggregation. In one such device, small-angle light scattering through rotating sample cuvettes is used to produce continuous records of aggregate growth (Thomas, 1980).

### Cell Phenotype

In tissue-engineering applications, particularly those in which cell-polymer hybrid materials are prepared, one is usually interested in promotion of some cell-specific function. For example, protein secretion and detoxification are essential functions for hepatocytes used for transplantation or liver support devices; therefore, measurements of protein secretion and intracellular enzyme activity (particularly the hepatic P<sub>450</sub> enzyme system) are frequently used to assess hepatocyte function. Similarly, the expression and activity of enzymes involved in neurotransmitter metabolism (such as choline acetyltransferase and tyrosine hydroxylase) are often used to assess the function of neurons. Production of extracellular matrix (ECM) proteins is important in the physiology of many cells; collagen and glycosaminoglycan production has been used as an indicator of cell function in chondrocytes, osteoblasts, and fibroblasts. In some cases, the important cell function involves the coordinated activity

of groups of cells, such as the formation of myotubules in embryonic muscle cell cultures, the contraction of the matrix surrounding the cells, or the coordinated contraction of cardiac muscle cells. In these cases, cell function is measured by observation of changes in morphology of cultured cells or cell communities.

### In Vivo Methods

The context of cell-polymer interactions *in vivo* is inherently complex, due to the presence of blood, interstitial fluids, and multiple cell types in various activation states. Proteins from the blood and interstitial fluid adsorb to polymer surfaces in a nonspecific manner and provide a substrate for cell adhesion (Ratner, 2004). Thus, it is believed that cells interact directly with this proteinaceous layer instead of the polymer surface, an assumption that explains the similar *in vivo* reactions elicited by a diverse array of polymers. Almost all implanted polymers induce a unique inflammatory response termed the *foreign-body response* (FBR) (Ratner, 2004).

The FBR can be divided into several overlapping phases that include nonspecific protein adsorption, inflammatory cell recruitment—predominantly of neutrophils and macrophages—macrophage fusion to form foreign-body giant cells (FBGC), and involvement of fibroblasts and endothelial cells (Fig. 20.1). The end result of the FBR is the formation of foreign-body giant cells directly on the polymer surface and the subsequent encapsulation of the implant by a fibrous capsule that is largely avascular. To date, the molecular and cellular determinants of the FBR remain largely unknown. However, recent studies have suggested specific roles for several proteins and a key role for macrophages in the FBR.

A number of implantation techniques in rodents and larger animals (typically rabbits, pigs, or sheep) have been adopted for the investigation of cell-polymer interactions. Most notably, short-term studies for the analysis of protein adsorption, inflammatory cell recruitment and adhesion, and macrophage fusion most often employ either intraperitoneal (IP) implantation or the subcutaneous (SC) cage implant, also known as the wound-chamber model. In the IP implant model, a sterilized piece of polymer is placed in the peritoneal cavity through a surgical incision (Tang *et al.*, 1998). This model has been used extensively in the investigation of protein adsorption onto polymer surfaces and its impact during the early inflammatory response (0–72 h). In general, due to the short duration of such studies, it is difficult to extrapolate the information obtained from such studies to the fate of the FBR. Implant studies of intermediate duration (days to weeks) have been executed using an SC cage implant; in this system, a polymer is placed within a cage made of stainless steel wire mesh and then implanted through a surgical incision (Kao *et al.*, 1995). The SC cage implant is useful because biologically active soluble agents

**FIG. 20.1.** Development of the foreign-body response. Representative images of hematoxylin and eosin-stained Millipore filter disks (mixed cellulose ester) implanted in the peritoneal cavity of wild-type mice. The number on each panel indicates the number of days after implantation. In the first two days following implantation, the discs display loose and expanding layers of attached inflammatory cells. Between four and eight days, the cell layers show increased organization that appears to coincide with the deposition of collagen fibers. Continuous deposition of collagenous matrix and an overall reduction in cellular content are characteristic of the two- and four-week time points. \* indicates the disc. Original magnification 400 $\times$ .

can be injected through the wire mesh in the immediate vicinity of the polymer.

Both IP and SC implantations allow for the analysis of recruited, nonadherent cell populations, which are collected by lavage of the peritoneal cavity or aspiration of host-derived exudates from the cage. In addition, implant materials can be recovered and analyzed for the presence of adherent cells by various techniques, immunohistochemistry being the most reliable. Thus, both implantation models can provide information regarding the migration of cells to the implantation site and the interaction of cells (adhesion, survival, fusion) with the polymer surface. Other commonly used *in vivo* models for the analysis of cell–polymer interactions involve the implantation of test polymers directly into host tissues such as dermis (subcutaneous), muscle, bone, and brain. Generally, such studies have been carried for longer incubation periods (weeks to months). Furthermore, polymer-based constructs have been surgically implanted at sites where they are expected to perform biological functions, for example, vascular grafts (L’Heureux *et al.*, 2006), heart valves (Vesely, 2005), and cardiac patches (Robinson *et al.*, 2005). Thus, in addition to biocompatibility and toxicity, polymers can be evaluated for their role in the function of a tissue or an organ. The direct implant model can be considered the most representative for most polymer applications and can provide information regarding the FBR, such as inflammation (FBGC formation), fibrosis (collagen content), encapsulation (capsule thickness), and angiogenesis (vascular density). Finally, in cases where the polymer is susceptible to degradation, additional analyses can be performed to evaluate the role of chemical and physical changes of the material in interactions with the tissue.

### III. CELL INTERACTIONS WITH POLYMERS

#### Protein Adsorption to Polymers

A polymeric material that is placed in solution or implanted in the body becomes coated with proteins quickly, usually within minutes. Many of the subsequent interactions of cells with the material depend on, or derive from, the composition of the protein layer that forms on the surface. Polymers have been shown to adsorb a large number of proteins *in vitro* (Andrade and Hlady, 1987). For example, proteomic analysis of PP,\* PET, and PDMS incubated with serum identified immunoglobulins, transferrin, albumin, serum amyloid P, and complement C4, among other proteins, on the polymer surface (Kim *et al.*, 2005). The C3 component of complement has also been shown to adsorb to medical-grade PEU, and adhesion of inflammatory cells to the polymer was reduced in the presence of C3-depleted serum but not fibronectin-depleted serum (Kao, 1999). In contrast, *in vivo* studies employing the IP implantation method suggest that adsorption of fibrinogen is the critical determinant of the FBR (Tang, 1993). Specifically, adsorption and denaturation of fibrinogen on polymer surfaces might lead to the exposure of cryptic cell adhesion motifs (integrin-binding sites) that influence subsequent cellular interactions.

#### Effect of Polymer Chemistry on Cell Behavior

##### Synthetic Polymers

For cells attached to a solid substrate, cell behavior and function depend on the characteristics of the substrate.

\* See Table 20.1 for abbreviations of polymers.

Consider, for example, experiments described by Folkman and Moscona, in which cells were allowed to settle onto surfaces formed by coating conventional tissue-culture polystyrene (TCPS) with various dilutions of pHEMA (Folkman and Moscona, 1978). As the amount of pHEMA added to the surface was increased, cell spreading decreased, as reflected by the average cell height on the surface. The degree of spreading, or average height, correlated with the rate of cell growth (Fig. 20.2), suggesting that cell shape, which was determined by the adhesiveness of the surface, modulated cell proliferation. In these experiments, two simple polymers (TCPS and pHEMA) were used to produce a series of surfaces with graded adhesivity, permitting the identification of an important aspect of cell physiology. These experiments clearly demonstrate that the nature of a polymer surface will have important consequences for cell function, an observation of considerable significance with regard to the use of polymers in tissue engineering.

Following an experimental design similar to that employed by Folkman and Moscona, a number of groups have examined the relationship between chemical or physical characteristics of the substrate and the behavior or function of attached cells. For example, in a study of cell adhesion, growth, and collagen synthesis on synthetic polymers, fetal fibroblasts from rat skin were seeded onto surfaces of 13 different polymeric materials (Tamada and Ikada, 1994). The polymer surfaces had a range of surface energies, as determined by static water contact angles, from very hydrophilic to very hydrophobic (Table 20.2). On a few of the surfaces (PVA and cellulose), little cell adhesion and no cell growth was observed. On most of the remaining surfaces,

however, a moderate fraction of the cells adhered to the surface and proliferated. The rate of proliferation was relatively insensitive to surface chemistry: The cell doubling time is ~24 hr, with slightly slower growth observed for two very hydrophobic surfaces (PTFE and PP; see Table 20.2). Collagen biosynthesis was also correlated with contact angle, with higher rates of collagen synthesis per cell for the most hydrophobic surfaces.

Results from a number of similar studies are summarized in Table 20.2. Cell adhesion appears to be maximized on surfaces with intermediate wettability (Fig. 20.3). For most surfaces, adhesion requires the presence of serum; therefore, this optimum is probably related to the ability of proteins to adsorb to the surface. In the absence of serum, adhesion is enhanced on positively charged surfaces. This general principle was further confirmed for cell spreading on copolymers of HEMA (hydrophilic) and EMA (hydrophobic), which was highest at an intermediate HEMA content, again corresponding to intermediate wettability (Horbett *et al.*, 1988); in this case, spreading correlated with fibronectin adsorption (Horbett and Schway, 1988). Similarly, the rate of fibroblast growth on polymer surfaces appears to be relatively independent of surface chemistry. Cell viability may also be related to interactions with the surface, although this is not yet predictable. The migration of surface-attached fibroblasts, endothelial cells, and corneal epithelial cells is also a function of polymer surface chemistry (Table 20.2).

### Surface Modification

Polymers can frequently be made more suitable for cell attachment and growth by surface modification. In fact, polystyrene (PS) substrates used for tissue culture are usually treated by glow discharge or exposure to chemicals, such as sulfuric acid, to increase the number of charged groups at the surface, which improves attachment and growth of many types of cells. Other polymers can also be modified in this manner. Treatment of pHEMA with sulfuric acid, for example, improves adhesion of endothelial cells and permits cell proliferation on the surface (Hannan and McAuslan, 1987). Modification of PS or PET by radio-frequency plasma deposition enhances attachment and spreading of fibroblasts and myoblasts (Chinn *et al.*, 1989). Again, the effects of these surface modifications appear to be secondary to increased adsorption of cell attachment proteins, such as fibronectin and vitronectin, to the surface. On the other hand, some reports have identified specific chemical groups at the polymer surface — such as hydroxyl (–OH) (Curtis, 1983) or surface C–O functionalities (Chinn *et al.*, 1989) — as important factors in modulating the fate of surface-attached cells.

So far, no general principles that would allow prediction of the extent of attachment, spreading, or growth of cultured cells on different polymer surfaces have been identified. Correlations have been made with parameters such as the density of surface hydroxyl groups (Curtis *et al.*, 1983),

**FIG. 20.2.** Cell shape and growth are modulated by properties of a polymer surface. Cell culture surfaces were produced by evaporating diluted solutions of pHEMA onto TCPS. The uptake of [ $^3$ H]thymidine was used as a measure of proliferation. The size of the symbol represents the relative cell height. Small symbols represent cells with small heights and therefore significant spreading; large symbols represent cells with large heights and therefore negligible spreading. Data replotted from Folkman and Moscona (1978).

density of surface sulfonic groups (Kowalczyńska and Kaminski, 1991), surface free energy (Schakenraad *et al.*, 1986; van der Valk *et al.*, 1983), fibronectin adsorption (Chinn *et al.*, 1989), and equilibrium water content (Lydon *et al.*, 1985) for specific cells, but exceptions to these correlations are always found. Perhaps general predictive correlations will emerge, as complete characterization of polymer systems—including bulk properties, surface chemical properties, and nanoscale topography (as described later)—are collected. But many commonly used polymer materials are complicated mixtures, containing components that are added to enhance polymerization or to impart desired physical properties, often in trace quantities. Lot-to-lot variations in the properties of commercially available polymers can be significant.

The surface chemistry of polymers appears to influence cell interactions *in vivo*. For example, the ability of macrophages to form multinucleated giant cells at the material surface correlates with the presence of certain chemical groups at the surface of hydrogels: Macrophage fusion decreases in the order  $(\text{CH}_3)_2\text{N} > -\text{OH} = -\text{CO}-\text{NH}- > -\text{SO}_3\text{H} > -\text{COOH} (-\text{COONa})$  (Smetana *et al.*, 1990). A similar hierarchy has been observed for CHO (Chinese hamster ovary) cell adhesion and growth on surfaces with grafted functional groups: CHO cell attachment and growth decreased in the order  $-\text{CH}_2\text{NH}_2 > -\text{CH}_2\text{OH} > -\text{CONH}_2 > -\text{COOH}$  (J. H. Lee *et al.*, 1994).

### Biodegradable Polymers

Biodegradable polymers slowly degrade and then dissolve following implantation. This feature may be important for many tissue-engineering applications, since the polymer

will disappear as functional tissue regenerates. For this reason, interactions of cells with a variety of biodegradable polymers have been studied. Biodegradable polymers may provide an additional level of control over cell interactions: During polymer degradation, the surface of the polymer is constantly renewed, providing a dynamic substrate for cell attachment and growth.

Homopolymers and copolymers of lactic and glycolic acid (PLA, PGA, PLGA) have been frequently examined as cell culture substrates, since they have been used as implanted sutures for several decades. Many types of cells will attach and grow on these materials. For example, chondrocytes proliferate and secrete glycosaminoglycans within porous meshes of PGA and foams of PLA (Freed *et al.*, 1993). Similarly, rat hepatocytes attach to blends of biodegradable PLGA polymers and secrete albumin when maintained in culture (Cima *et al.*, 1991). Neonatal rat osteoblasts also attach to PLA, PGA, and PLGA substrates and synthesize collagen in culture (Ishaug *et al.*, 1994).

Cell adhesion and function have been examined on materials made from other biodegradable polymers. As an example, cells from an osteogenic cell line attach onto polyphosphazenes produced with a variety of side groups; the rate of cell growth as well as the rate of polymer degradation depend on side-group chemistry (Laurencin *et al.*, 1993).

Use of degradable polymers increases the complexity analysis in the *in vivo* setting because their degradation products can cause excessive and prolonged biological responses. Depending on the material used, degradation products can be released by hydrolysis, enzymatic digestion, degradative activity of macrophages and FBGC, or combinations of these mechanisms. The effects of polymer-derived products that are released by hydrolysis or enzymatic digestion depend on the chemical properties of the polymer and are not difficult to determine. On the other hand, the effects of products released due to cellular activities are difficult to predict, because the chemical and biological mechanisms responsible for their generation and release have not been established. Furthermore, the activity of cells, and thus the rate of release, can be influenced by several parameters, such as local concentrations of growth factors. It is expected that biodegradable polymers should allow for the favorable resolution of the FBR following their complete removal from the host tissue. The disappearance of FBGC from implantation sites following degradation of polymers to microparticles smaller than 10  $\mu\text{m}$  in size has been observed (Kyriakides *et al.*, unpublished data). Furthermore, macrophages were observed to persist until the degradation of the polymer was complete. In SC implantation sites the formation of a vascularized collagenous work as a replacement for the polymer was observed. Presumably, the physiology of the implantation site, the acuteness of the inflammatory response, and the rate of polymer degradation all influence the nature of the FBR. Favorable *in vivo* results have been obtained with biodegradable elastomeric

polyesters composed of poly(diols citrates) (J. Yang *et al.*, 2006). However, the duration of the FBR was shown to exceed 12 mo in implanted compressed naltrexone-poly[trans-3, 6-dimethyl-1, 4-dioxane-2, 5-dione] (DL-lactide) loaded microspheres (Hulse *et al.*, 2005).

### Synthetic Polymers with Adsorbed Proteins

As mentioned earlier, cell interactions with polymer surfaces appear to be mediated by proteins adsorbed from the local environment. Since it is difficult to study these effects *in situ* during cell culture, often the polymer surfaces are pretreated with purified protein solutions. In this way, the investigators hope that subsequent cell behavior on the surface will represent cell behavior in the presence of a stable layer of surface-bound protein. A major problem with this approach is the difficulty in determining whether surface conditions, i.e., the density of protein on the surface, change during the period of the experiment.

As described earlier, cell spreading, but not attachment, correlates with fibronectin adsorption to a variety of surfaces. Rates of cell migration on a polymer surface are usually sensitive to the concentration of preadsorbed adhesive proteins (Calof, 1991), and migration can be modified by addition of soluble inhibitors to cell adhesion (Wu *et al.*, 1994). It appears that the rate of migration is optimal at intermediate substrate adhesiveness, as one would expect from mathematical models of cell migration (Lauffenburger and Linderman, 1993). In fact, a recent study shows a clear correlation between adhesiveness and migration for CHO cells (Palecek *et al.*, 1997).

The outgrowth of corneal epithelial cells from explanted rabbit corneal tissue has been used as an indicator of cell attachment and migration on biomaterial surfaces (Pettit *et al.*, 1990). When corneal cell outgrowth was measured on 10 different materials that were preadsorbed with fibronectin, outgrowth generally increased with the ability of fibronectin to adsorb to the material (Table 20.2, footnote j). Exceptions to this general trend could be found, suggesting that other factors (perhaps stability of the adsorbed protein layer) are also important.

### Hybrid Polymers with Immobilized Functional Groups

Surface modification techniques have been used to produce polymers with surface properties that are more suitable for cell attachment (Ikada, 1994). For example, chemical groups can be added to change the wettability of the surface, which often influences cell adhesion (Fig. 20.3), as described earlier. Alternatively, whole proteins, such as collagen, can be immobilized to the surface, providing the cell with a substrate that more closely resembles the ECM found in tissues. Collagen and other ECM molecules have also been incorporated into hydrogels either by adding the protein to a reaction mixture containing monomers and initiating the radical polymerization or by mixing the protein with polymerized polymer, such as pHEMA, in appropriate

solvents. To isolate certain features of ECM molecules and to produce surfaces that are simpler and easier to characterize, smaller biologically active functional groups have been used to modify surfaces. These biologically active groups can be oligopeptides, saccharides, or glycolipids.

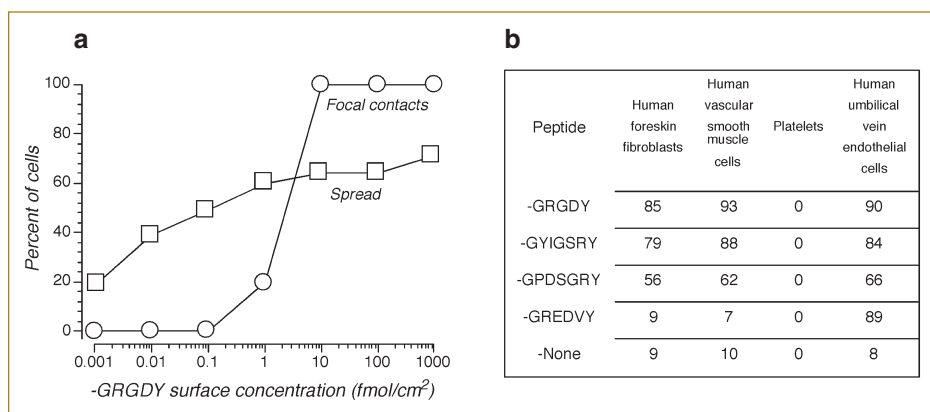

Certain short amino acid sequences, identified by analysis of active fragments of ECM molecules, appear to bind to receptors on cell surfaces and mediate cell adhesion. For example, the cell-binding domain of fibronectin contains the tripeptide RGD (Arg-Gly-Asp) (Pierschbacher and Ruoslahti, 1984).<sup>\*</sup> Cells attach to surfaces containing adsorbed oligopeptides with the RGD sequence, and soluble, synthetic peptides containing the RGD sequence reduce the cell-binding activity of fibronectin, demonstrating the importance of this sequence in the adhesion of cultured cells. A large number of ECM proteins (fibronectin, collagen, vitronectin, thrombospondin, tenascin, laminin, and entactin) contain the RGD sequence. The sequences YIGSR and IKVAV on the A chain of laminin also have cell-binding activity and appear to mediate adhesion in certain cells.

Because RGD appears to be critical in cell adhesion to ECM, many investigators have examined the addition of this sequence to synthetic polymer substrates. The addition of cell-binding peptides to a polymer can induce cell adhesion to otherwise nonadhesive or weakly adhesive surfaces. Cell spreading and focal contact formation are also modulated by the addition of peptide (Fig. 20.4). Since cells contain cell adhesion receptors that recognize only certain ECM molecules, use of an appropriate cell-binding sequence can lead to cell-selective surfaces, where the population of the cells that adhere to the polymer is determined by the peptide (Hubbell *et al.*, 1991).

The presence of serum proteins attenuates the adhesion activity of peptide-grafted PEU surfaces (Lin *et al.*, 1994), highlighting a difficulty in using these peptide-grafted materials *in vivo*. This problem may be overcome, however, through the development of base materials that are biocompatible yet resistant to protein adsorption. One of the most successful approaches for reducing protein adsorption or cell adhesion is to produce a surface rich in PEG. A variety of techniques have been used, including surface grafting of PEG, adsorption of PEG-containing copolymers, semi-interpenetrating networks, and immobilization of PEG-star polymers to increase the density of PEG chains at the surface.

Alternatively, matrices formed directly from synthetic polypeptides may also be useful for cell adhesion. Genes coding the  $\beta$ -sheet of silkworm silk have been combined with genes coding fragments of fibronectin to produce

<sup>\*</sup> Amino acids are identified by their one-letter abbreviations: A = alanine, R = arginine, N = asparagine, D = aspartic acid, B = asparagine or aspartic acid, C = cysteine, Q = glutamine, E = glutamic acid, Z = glutamine or glutamic acid, G = glycine, H = histidine, I = isoleucine, L = leucine, K = lysine, M = methionine, F = phenylalanine, P = proline, S = serine, T = threonine, W = tryptophan, Y = tyrosine, V = valine.

**FIG. 20.4.** Cell adhesion to surfaces with immobilized peptides. Data from Hubbell *et al.* (1991); Massia and Hubbell (1991). **(a)** Fibroblast spreading on surfaces with immobilized -GRGDY. **(b)** Cell-selective surfaces: fraction of cells spread for several immobilized peptides.

proteins that form very stable matrices with cell adhesion domains (Pronectin F, Sanyo Chemical, Inc.). Synthetic proteins based on peptide sequences from elastin have been used as cell culture substrates: In the presence of serum, fibroblasts and endothelial cells adhered to the surfaces of matrices formed by  $\gamma$ -irradiation cross-linking of polypeptides containing repeated sequences GGAP, GGVP, GGIP, and GVGVP (Nicol *et al.*, 1993).

Surface adsorption of homopolymers of basic amino acids, such as polylysine and polyornithine, are frequently used to enhance cell adhesion and growth on polymer surfaces. Similarly, covalently bound amine groups can also influence cell attachment and growth. Polymerization of styrene with monamine- or diamine-containing monomers produced copolymers with ~8% mono- or diamine side chains, which enhanced spreading and growth: diamine-PS > monoamine-PS > PS (Kikuchi *et al.*, 1992).

The immobilization of saccharide units to polymers can also influence cell attachment and function. As an example, *N-p*-vinylbenzyl- $\alpha$ -D-galactopyranosyl-(1-4)-D-gluconamide has been polymerized to form a polymer with a polystyrene backbone and pendant lactose functionalities (Kobayashi *et al.*, 1992). Rat hepatocytes adhere to surfaces formed from this polymer, via asialoglycoprotein receptors on the cell surface, and remain in a rounded morphology consistent with enhanced function in culture. In the absence of serum, rat hepatocytes will adhere to similar polymers with pendant glucose, maltose, or maltotriose. Similar results have been obtained with polymer surfaces derivatized with *N*-acetyl glucosamine, which is recognized by a surface lectin on chicken hepatocytes (Gutsche *et al.*, 1994).

### Electrically Charged or Electrically Conducting Polymers

A few studies have examined cell growth and function on polymers that are electrically charged. Piezoelectric polymer films, which were produced by high-intensity corona poling of poly(vinylidene fluoride) or poly(vinylidene fluoride-co-trifluoroethylene) and should generate transient surface charge in response to mechanical forces,

enhanced the attachment and differentiation of mouse neuroblastoma cells (Nb2a), as determined by neurite number and mean neurite length (Valentini *et al.*, 1992). These observations may be important *in vivo*, as well. For example, positively poled poly(vinylidene fluoride-co-trifluoroethylene) nerve guidance channels produced greater numbers of myelinated axons than either negatively poled or unpoled channels (Fine *et al.*, 1991). Electrically conducting polymers might be useful for tissue-engineering applications, because their surface properties can be changed by application of an applied potential. For example, endothelial cells attached and spread on fibronectin-coated polypyrrole films in the oxidized state, but they became rounded and ceased DNA synthesis when the surface was electrically reduced (Wong *et al.*, 1994).

### Influence of Surface Morphology on Cell Behavior

The microscale texture of an implanted material can have a significant effect on the behavior of cells in the region of the implant. This has long been observed *in vivo*. For example, fibrosarcomas developed with high frequency, approaching 50% in certain situations, around implanted Millipore filters; the tumor incidence increased with decreasing pore size in the range of 450–50  $\mu$ m (Goldhaber, 1961).

The behavior of cultured cells on surfaces with edges, grooves, or other textures is different than behavior on smooth surfaces. In many cases, cells oriented and migrated along fibers or ridges in the surface, a phenomenon called *contact guidance*, from early studies on neuronal cell cultures (Weiss, 1934). Fibroblasts orient on grooved surfaces (Brunette, 1986), particularly when the texture dimensions are 1–8  $\mu$ m (Dunn and Brown, 1986). The degree of cell orientation depends on both the depth and the pitch of the grooves. Not all cells exhibit the same degree of contact guidance when cultured on identical surfaces: BHK and MDCK cells orient on 100-nm-scale grooves in fused quartz, while cerebral neurons do not (Clark *et al.*, 1991). Fibroblasts, monocytes and macrophages, but not keratinocytes or neutrophils, spread when cultured on silicon oxide with grooves with a 1.2- $\mu$ m depth and a 0.9- $\mu$ m pitch (Meyle

*et al.*, 1995). The variation in responses to surfaces with grooves and edges is shown in Table 20.3.

Substrates with peaks and valleys also influence the function of attached cells (Schmidt and von Recum, 1992). PDMS surfaces with 2- to 5- $\mu\text{m}$  texture maximized macrophage spreading. Similarly, PDMS surfaces with 4- or 25- $\mu\text{m}^2$  peaks uniformly distributed on the surface provided better fibroblast growth than 100- $\mu\text{m}^2$  peaks or 4-, 25-, or 100- $\mu\text{m}^2$  valleys.

The microscale structure of a surface has a significant effect on cell migration, at least for the migration of human neutrophils. In one study, microfabrication technology was used to create regular arrays of micron-size holes ( $2\ \mu\text{m} \times 2\ \mu\text{m} \times 210\ \text{nm}$ ) on fused quartz and photosensitive polyimide surfaces (Tan *et al.*, 2001). The patterned surfaces, which possessed a basic structural element of a three-dimensional network (i.e., spatially separated mechanical edges), were used as a model system for studying the effect of substrate microgeometry on neutrophil migration. The edge-to-edge spacing between features was systematically varied from 6  $\mu\text{m}$  to 14  $\mu\text{m}$  with an increment of 2  $\mu\text{m}$ . The presence of evenly distributed holes at the optimal spacing of 10  $\mu\text{m}$  enhanced  $\mu$  by a factor of 2 on polyimide, a factor of 2.5 on collagen-coated quartz, and a factor of 10 on uncoated quartz. The biphasic dependence on the mechanical edges of neutrophil migration on two-dimensional patterned substrate was strikingly similar to that previously observed during neutrophil migration within three-dimensional networks, suggesting that microfabricated materials provide relevant models of three-dimensional structures with precisely defined physical characteristics. Perhaps more importantly, these results illustrate that the microgeometry of a substrate, when considered separately from adhesion, can play a significant role in cell migration.

#### Use of Patterned Surfaces to Control Cell Behavior

A variety of techniques have been used to create patterned surfaces containing cell adhesive and nonadhesive regions. Patterned surfaces are useful for examining fundamental determinants of cell adhesion, growth, and function. For example, individual fibroblasts were attached to adhesive microislands of palladium that were patterned onto a nonadhesive pHEMA substrate using microlithographic techniques (O'Neill *et al.*, 1986). By varying the size of the microisland, the extent of spreading and hence the surface area of the cell was controlled. On small islands ( $\sim 500\ \mu\text{m}^2$ ), cells attached but did not spread. On larger islands ( $4000\ \mu\text{m}^2$ ), cells spread to the same extent as in unconfined monolayer culture. Cells on large islands proliferate at the same rate as cells in conventional culture, and most cells attached to small islands proliferate at the same rate as suspended cells. For 3T3 cells, however, contact with the surface enhanced proliferation, suggesting that anchorage can stimulate cell division by simple contact with the substrate as well as by increases in spreading.

A number of other studies have employed patterned surfaces in cell culture. Micrometer-scale adhesive islands of self-assembled alkanethiols were created on gold surfaces using a simple stamping procedure (Singhvi *et al.*, 1994), which served to confine cell-spreading islands. When hepatocytes were attached to these surfaces, larger islands ( $10,000\ \mu\text{m}^2$ ) promoted growth, while smaller islands ( $1600\ \mu\text{m}^2$ ) promoted albumin secretion. Stripes of a monoamine-derivatized surface were produced on fluorinated ethylene propylene films by radio-frequency glow discharge (Ranieri *et al.*, 1993). Since proteins adsorbed differently to the monoamine-derivatized and the untreated stripes, striped patterns of cell attachment were produced. A similar approach, using photolithography to produce hydrophilic patterns on a hydrophobic surface, produced complex patterns of neuroblastoma attachment and neurite extension (Matsuda *et al.*, 1992). A variety of substrate microgeometries were created by photochemical fixation of hydrophilic polymers onto TCPS or hydrophobic polymers onto PVA through patterned photomasks: Bovine endothelial cells attached and proliferated preferentially on either the TCPS surface (on TCPS/hydrophilic patterns) or the hydrophobic surface (on PVA/hydrophobic patterns) (Matsuda and Sugawara, 1995). When chemically patterned substrates were produced on self-assembled monolayer films using microlithographic techniques, neuroblastoma cells attached to and remained confined within amine-rich patterns on these substrates (Matsuzawa *et al.*, 1993).

## IV. CELL INTERACTIONS WITH POLYMERS IN SUSPENSION

Most of the studies reviewed in the preceding section concerned the growth, migration, and function of cells attached to a solid polymer surface. This is a relevant paradigm for a variety of tissue-engineering applications where polymers will be used as substrates for the transplantation of cells or as scaffolds to guide tissue regeneration *in situ*. Polymers may be important in other aspects of tissue engineering, as well. For example, polymer microcarriers can serve as substrates for the suspension culture of anchorage-dependent cells, and therefore they might be valuable for the *in vitro* expansion of cells or cell transplantation (Demetriou *et al.*, 1986). In addition, immunoprotection of cells suspended within semipermeable polymer membranes is another important approach in tissue engineering, since these encapsulated cells may secrete locally active proteins or function as small endocrine organs within the body.

The idea of using polymer microspheres as particulate carriers for the suspension culture of anchorage-dependent cells was introduced by van Wezel (1967). As already described for planar polymer surfaces, the surface characteristics of microcarriers influence cell attachment, growth, and function. In the earliest studies, microspheres composed of diethylaminoethyl (DEAE)-dextran were used; these spheres have a positively charged surface and are

**Table 20.3.** Summary of the effect of parallel ridges/grooves on cell behavior

<i>Cells</i>	<i>Material</i>	<i>h/d (μm)</i>	<i>w (μm)</i>	<i>s (μm)</i>	<i>Result</i>
Chick heart fibroblasts (Dunn, 1982)	Glass	*	2	2	Not aligned
		*	4	4–12	Aligned
Human gingival fibroblasts (Brunette, 1986)	Epon	5	36–78	36–78	Aligned
		92	100–162	101–162	Not aligned
Teleost fin mesenchymal cells (Wagers <i>et al.</i> , 2002)	Quartz	0.8–1.1	1–4	1–4	Aligned with increasing width
BHK, MDCK, and Chick embryo neurites (Clark <i>et al.</i> , 1990)	Silicon or ECM protein-coated silicon	0.2–1.9	2–12	2–12	Aligned with increasing depth, and alignment depended on depth
Hippocampal neurons (Rajnicek <i>et al.</i> , 1997)	Quartz	0.014	1	1	Not aligned
		1.1	4	4	Aligned
<i>Xenopus</i> spinal cord neurons (Rajnicek <i>et al.</i> , 1997)	Quartz	0.014–1.1	1–4	1–4	Aligned
Epithelial tissue and cells (Dalton <i>et al.</i> , 2001)	Polystyrene	1 or 5	1–10	1–10	Migration was enhanced along the grooves; more significant effect on deeper grooves
Osteoblasts (Perizzolo <i>et al.</i> , 2001)	Ti- or Ca-P-coated silicon	3, 10, or 30	5	42	Aligned and increased bonelike nodule formation
Murine macrophage P388D1 (Wojciak-Stothard <i>et al.</i> , 1996)	Fused silica or ECM protein-coated silica	0.03–0.282	2 or 10	*	Aligned with increasing depth or decreasing width
Human neutrophils (Tan and Saltzman, 2002)	Silicon and silicon coated with metals	3, 5	2	6–14	Rate of migration depended on <i>s</i>
Bovine pulmonary artery smooth muscle cells (Hu <i>et al.</i> , 2005)	Polystyrene	0.2–0.9	0.1–10	0.1–10	Alignment of attached cells, which was enhanced on the nanoscale features

routinely used as anion-exchange resins. DEAE-dextran microcarriers support the attachment and growth of both primary cells and cell lines, particularly when the surface charge is optimized. In addition to dextran-based microcarriers, microspheres that support cell attachment can be produced from PS, gelatin, and many of the synthetic and naturally occurring polymers described in the preceding sections. The surface of the microcarrier can be modified chemically or by immobilization of proteins, peptides, or carbohydrates.

Suspension culture techniques can be used to permit cell interactions with complex three-dimensional polymer formulations, as well. For example, cells seeding onto polymer fiber meshes during suspension culture often result in more uniform cell distribution within the mesh than can be obtained by inoculation in static culture (Freed and Vunjak-Novakovic, 1995).

In cell encapsulation techniques, cells are suspended within thin-walled capsules or solid matrices of polymer. Alginate forms a gel with the addition of divalent cations under very gentle conditions and, therefore, has been frequently used for cell encapsulation. Certain synthetic polymers, such as polyphosphazenes, can also be used to encapsulate cells by cation-induced gelation. Low-melting-temperature agarose has also been studied extensively for cell encapsulation. Methods for the microencapsulation of cells within hydrophilic or hydrophobic polyacrylates by interfacial precipitation have been described (Dawson *et al.*, 1987), although the thickness of the capsule can limit the permeation of compounds, including oxygen, through the semipermeable membrane shell. Interfacial polymerization can be used to produce conformal membranes on cells or cell clusters (Sawhney *et al.*, 1994), thereby providing immunoprotection while reducing diffusional distances.

Hollow fibers are frequently used for macroencapsulation; cells and cell aggregates are suspended within thin fibers composed of a porous, semipermeable polymer. Chromaffin cells suspended within hollow fibers formed from copolymer of vinyl chloride and acrylonitrile, which are commonly used as ultrafiltration membranes, have been studied as potential treatments for cancer patients with pain (Joseph *et al.*, 1994), Alzheimer's disease (Emerich *et al.*, 1994), and retinitis pigmentosa (Tao *et al.*, 2002). Other polymer materials — such as chitosan, alginate, and agar — have been added to the interior of the hollow fibers to provide an internal matrix that enhances cell function or growth.

## V. CELL INTERACTIONS WITH THREE-DIMENSIONAL POLYMER SCAFFOLDS AND GELS

Cells within tissues encounter a complex chemical and physical environment that is quite different from commonly used cell culture conditions. Three-dimensional cell culture methods are frequently used to simulate the chemical and

physical environment of tissues. Often, tissue-derived cells cultured in ECM gels will reform multicellular structures that are reminiscent of tissue architecture.

Gels of agarose have also been used for three-dimensional cell culture. Chondrocytes dedifferentiate when cultured as monolayers, but they reexpress a differentiated phenotype when cultured in agarose gels (Benya and Shaffer, 1982). When fetal striatal cells are suspended in three-dimensional gels of hydroxylated agarose, ~50% of the cells extended neurites in gels containing between 0.5% and 1.25% agarose, but no cells extended neurites at concentrations above 1.5%. This inhibition of neurite outgrowth correlates with an average pore radius of greater than 150 nm (Bellamkonda *et al.*, 1995). Neurites produced by PC12 cells within agarose gels, even under optimal conditions, are much shorter and fewer in number than neurites produced in gels composed of ECM molecules (Krewson *et al.*, 1994).

Macroporous hydrogels can also be produced from pHEMA-based materials, using either freeze-thaw or porosity techniques. These materials, when seeded with chondrocytes, may be useful for cartilage replacement (Corkhill *et al.*, 1993). Similar structures may be produced from PVA by freeze-thaw cross-linking. Recently, a PEG-based macroporous gel was used as a scaffold for endothelial cells to form microvessel networks *in vivo* (Ford *et al.*, 2006). Although cells adhere poorly to pHEMA, PVA, and PEG materials, adhesion proteins or charged polymers can be added during the formation to encourage cell attachment and growth. Alternatively, water-soluble, nonadhesive polymers containing adhesive peptides, such as RGDS, can be photopolymerized to form a gel matrix around cells (see Moghaddam and Matsuda, 1991, for example).

Fiber meshes and foams of PLGA, PLA, and PGA have been used to create three-dimensional environments for cell proliferation and function and to provide structural scaffolds for tissue regeneration. When cultured on three-dimensional PGA fiber meshes, chondrocytes proliferate, produce both glycosaminoglycans and collagen, and form structures that are histologically similar to cartilage (Puelacher *et al.*, 1994). The internal structure of the material as well as the physical dimensions of the polymer fiber mesh influence cell growth rate, with slower growth in thicker meshes. Changing the fluid mechanical forces on the cells during the tissue formation also appears to influence the development of tissue structure.

In addition to fiber meshes, porosity can be introduced into polymer films by phase separation, freeze-drying, salt leaching, and a variety of other methods (reviewed in S. Yang *et al.*, 2001). It is now possible to make porous, degradable scaffolds with controlled pore architectures and oriented pores (Ma and Choi, 2001; Teng *et al.*, 2002). Fabrication methods that provide control over the structure at different length scales may be useful in the production of three-dimensional tissue-like structures.

Most methods for producing fiber meshes are limited to producing fibers ~10 microns in diameter, which is much larger than the diameter of natural fibers that occur in the extracellular matrix and also larger than many of the features that are known to be important in orienting or guiding cell activity (Table 20.3). Electrospinning techniques can be used to make small-diameter fibers and nonwoven meshes of a variety of materials, including poly(caprolactone), PLA, collagen, and elastin-mimetic polymers.

## VI. CELL INTERACTIONS UNIQUE TO THE *IN VIVO* SETTING

While cell interactions with polymers *in vitro* can be described by examination of cell behaviors—such as adhesion, migration, and gene expression—or the coordinated behavior of cell groups—such as aggregation, cell interactions with polymers *in vivo* can lead to other responses, involving cells that are recruited to the implantation site and remodeling of the tissue space surrounding, or even within, the polymeric material. Inflammation, the foreign-body response, and angiogenesis are three examples of these more global responses to an implanted material.

There is much still to learn in this area, but it is clear that both the implant material and the physiology of the implant site are important variables. A recent paper describing a relatively simple experiment, in which ePTFE implants were placed in adipose tissue, in subcutaneous tissue, or epicardially, illustrates the variability of these responses (Kellar *et al.*, 2002). This short section introduces these physiological responses to implanted materials.

### Inflammation

The implantation of polymers through surgical incisions means that an initial component of the FBR involves a wound healing-like response, and it is reasonable to assume that the early inflammatory response is mediated, at least in part, by wound-derived factors. Analysis of inflammatory cells has been pursued in several implantation models and was shown to involve predominantly neutrophils (early) and monocyte/macrophages (late). Subsequent to their recruitment, these cells are believed to utilize adhesion receptors to interact with adsorbed proteins. Studies in mice that lack specific integrins or fibrinogen have provided supporting evidence for this hypothesis (Busuttill *et al.*, 2004; Lu *et al.*, 1997). Specifically, short-term (18-h) IP implantation of polyethylene terephthalate (PET) discs in mice that lack fibrinogen indicated normal recruitment but reduced adhesion of macrophages and neutrophils to the polymer. In the same study, analysis of the response in mice that lack plasminogen indicated no changes in cell adhesion to the polymer, despite a reduction in the recruitment of both cell types in the peritoneal cavity. Thus, in

addition to fibrinogen for adhesion, inflammatory cells can utilize plasminogen for migration/recruitment. Surprisingly, the chemokine CCL2 (also known as monocyte chemoattractant protein, or MCP-1) was shown not to be important in monocyte/macrophage recruitment in long-term implants (Kyriakides *et al.*, 2004). However, CCL2 was shown to be important for macrophage fusion leading to FBGC formation. FBGC can cause damage to polymer surfaces through their degradative and phagocytic activities and, thus, pose a significant obstacle to the successful application of polymer-based biomaterials and devices. *In vivo* studies have identified a critical role for interleukin (IL)-4 in the formation of FBGC (Kao *et al.*, 1995), but little is known about the regulation of macrophage fusion. On the other hand, several studies have focused on the role of polymer surface chemistry on macrophage function and FBGC formation. For example, analysis of macrophage adhesion, apoptosis, and fusion on hydrophobic (PET- and BDEDTC-coated), hydrophilic (PAAm), anionic (PAANA), and cationic (DMAAPAAmMel) surfaces implanted in the rat cage implant model revealed that PAAm and PAANA induced more apoptosis and reduced adhesion and fusion (Christenson *et al.*, 2005).

### Fibrosis and Angiogenesis

Unlike wound healing, the resolution of the polymer-associated inflammatory response is characterized by the excessive deposition of a highly organized collagenous matrix and a striking paucity of blood vessels (Kyriakides and Bornstein, 2003; Mikos *et al.*, 1998). The collagenous capsule can vary in thickness but usually exceeds 100  $\mu\text{m}$ , presumably to limit diffusion of small molecules to and from the polymer. The dense and organized nature of the collagen fibers in the capsule could play a role in limiting blood vessel formation. Implantation studies in mice that lack the angiogenesis inhibitor TSP2 indicated that an increase in vascular density in capsules surrounding PDMS discs was associated with significant loosening of the collagenous matrix (Kyriakides *et al.*, 1999). However, a direct link between the arrangement of collagen fibers in the capsule and blood vessel formation has not been established. Interestingly, the modification of the PDMS surface from a hydrophobic to a hydrophilic state altered its cell adhesive properties *in vitro* but did not cause a change in the FBR *in vivo* (Kyriakides *et al.*, 1999). Such observations underscore the significance of *in vivo* evaluation of cell- and tissue-polymer interactions. Reduced encapsulation of polydimethylsiloxane (silicone rubber) discs and cellulose Millipore filters implanted SC has been reported in mice that lack SPARC (secreted protein, acidic and rich in cysteine), a matricellular glycoprotein that modulates the interactions of cells with the extracellular matrix. Interestingly, mice that lack SPARC and its close homolog, hevin, display diminished vascular density in encapsulated Millipore filters (type HA, mixed cellulose ester) (Barker *et al.*, 2005). Taken together,

implantation studies in genetically modified mice suggest that members of the matricellular protein group play critical roles in the FBR (Kyriakides and Bornstein, 2003). The process however, can also be influenced by parameters such as polymer special geometry and porosity. Comparison of the FBR elicited by expanded and condensed PTFE showed similar encapsulation but more mature fibrous capsule formation in the latter (Voskerician *et al.*, 2006). In addition, the effect of polymer porosity in the FBR was examined in SC-implanted PTFE membranes in rats, where it was shown that

the vascular density could be increased in capsules surrounding polymers with a pore size in the range of 5  $\mu\text{m}$  (Brauker *et al.*, 1995). However, it is unclear whether the same porosity would enhance the vascular density of capsules surrounding other polymers. Finally, an additional concern with polymer encapsulation is the presence of contractile cells, myofibroblasts, which can cause contraction of the capsule and misshape or damage polymer implants. For example, silicone-based breast implants have been shown to be susceptible to this phenomenon (Granchi *et al.*, 1995).

### I. INTRODUCTION

The extracellular matrix is a complex chemically and physically cross-linked network of proteins and glycosaminoglycans. The matrix serves to organize cells in space, to provide them with environmental signals to direct site-specific cellular regulation, and to separate one tissue space from another. The interaction between cells and the extracellular matrix is bidirectional and dynamic: Cells are constantly accepting information on their environment from cues in the extracellular matrix, and cells are frequently remodeling their extracellular matrix. In this chapter, the proteins in the extracellular matrix and their cell surface receptors are introduced, and mechanisms by which cells transduce chemical information in their extracellular matrix are discussed. Methods for spatially displaying matrix recognition factors on and in biomaterials are described, both in the context of model systems for investigation of cellular behavior and from the perspective of the creation of bioactive biomaterials for tissue-engineering therapies.

The extracellular matrix serves at least three functions in its role of controlling cell behavior: It provides adhesion signals, it provides growth factor-binding sites, and it provides degradation sites to give way to the enzymatic activity of cells as they migrate. An understanding of these interactions is important in tissue engineering, where one may desire to mimic the biological recognition molecules that control the relationships between cells and their natural bio-

material interface, namely the extracellular matrix. The components of the extracellular matrix are on one level immobilized, but not necessarily irreversibly. Cell-derived enzymes, such as tissue transglutaminase and lysyl oxidase, serve chemically to cross-link certain components of the extracellular matrix, such as fibronectin chains to other fibronectin chains and to fibrillar collagen chains. Other components are more transiently immobilized, such as growth factors within the extracellular matrix proteoglycan network. This network can be partially degraded, and the growth factors themselves can be proteolytically cleaved, to mobilize the growth factors under cellular control. Not all of the signals of the extracellular matrix are biochemical in nature. A biomechanical interplay between cells and their extracellular matrix also plays an important role in the functional regulation in many tissues, particular in load-bearing tissues. This chapter considers only the biochemical aspects of biological recognition; the reader is referred elsewhere for treatments of the role of the extracellular matrix as a biomechanical regulator of cell behavior (Grinnell, 2003; Discher *et al.*, 2005).

### II. EXTRACELLULAR MATRIX PROTEINS AND THEIR RECEPTORS

Interactions between cells and the extracellular matrix are mediated by cell surface glycoprotein and proteoglycan receptors interacting with proteins bound within the extra-

cellular matrix. This section begins with an introduction of the glycoprotein receptors on cell surfaces involved in cell adhesion. The discussion then turns to the proteins in the extracellular matrix to which those receptors bind, including the active domains of those proteins that bind to the cell surface receptors. Finally, the roles of cell surface-associated enzymes in the processing and remodeling of the extracellular matrix are addressed.

Four major classes of glycoprotein adhesion receptors are present on cell surfaces, three of which are involved primarily in cell–cell adhesion and one of which is involved in both cell adhesion to other cells and cell adhesion to the extracellular matrix. The first three are introduced briefly and the fourth more extensively.

The cadherins are a family of cell surface receptors that participate in homophilic binding (i.e., the binding of a cadherin on one cell with an identical cadherin on another cell) (Gumbiner, 2005; Leckband and Prakasam, 2006). These molecules allow a cell of one type (e.g., endothelial cells) to recognize other cells of the same type and are important in the early stages of organogenesis. These interactions depend on the presence of extracellular  $\text{Ca}^{++}$  and may be dissociated by calcium ion chelation. Since all cadherins are present on cell surfaces, cadherins are not involved directly in cell interactions with the extracellular matrix. They may be involved indirectly, in that they may organize cell–cell contacts in concert with another receptor system that is involved in regulation of cell–extracellular matrix binding.

A second class of receptors is the selectin family (Vestweber and Blanks, 1999). These membrane-bound proteins are involved in heterophilic binding between cells, such as blood cells and endothelial cells, in a manner that depends, as with the cadherins, on extracellular  $\text{Ca}^{++}$ . These proteins contain lectin-like features and recognize branched oligosaccharide structures in their ligands, namely the sialyl Lewis X and the sialyl Lewis A structures. As with the cadherins, these receptor–ligand interactions are important primarily in cell–cell interactions, and they are particularly important in the context of inflammation.

A third class of receptors represents members of the immunoglobulin superfamily, cell adhesion molecule proteins that are denoted as Ig-CAMs or simply CAMs (Walsh and Doherty, 1997). These proteins bind their protein ligands in a manner that is independent of extracellular  $\text{Ca}^{++}$ , and they participate in both homophilic and heterophilic interactions. As for the cadherins and the selectins, they bind to other cell surface proteins and are thus primarily involved in cell–cell interactions. One class of ligand for these receptors includes selected members of the integrin class of adhesion receptors, discussed later.

The fourth class of adhesion receptors is the integrin family (van der Flier and Sonnenberg, 2001; Bokel and Brown, 2002; Arnaout *et al.*, 2005; Ginsberg *et al.*, 2005; Wiesner *et al.*, 2005). While the other three classes of receptors just described briefly are involved primarily in cell–cell recognition, the integrins are involved in both cell–cell and cell–

extracellular matrix binding. The integrins are dimeric proteins, consisting of an  $\alpha$  and a  $\beta$  subunit assembled non-covalently into an active dimer. There are many known  $\alpha$  and  $\beta$  subunits, with at least 18 such  $\alpha$  subunits and eight such  $\beta$  subunits that are capable of assembly into at least 24  $\alpha\beta$  combinations. Some of the  $\alpha\beta$  combinations present in the  $\beta_1$ ,  $\beta_2$ ,  $\beta_3$ , and  $\beta_4$  subclasses are shown in Table 21.1; these are the most commonly expressed integrins and are thus arguably the most generally important. The  $\beta_2$  integrins are involved primarily in cell–cell recognition; for example, the integrin  $\alpha_L\beta_2$  binds to ICAM-1 and ICAM-2, both members of the immunoglobulin superfamily subclass of cell adhesion molecules described in the preceding paragraph. By contrast, the  $\beta_1$ ,  $\beta_3$ , and  $\beta_4$  integrins are involved primarily in cell–extracellular matrix interactions.

The  $\beta_1$  and  $\beta_3$  integrins bind to numerous proteins present in the extracellular matrix, as illustrated in Table 21.1. These proteins include collagen, fibronectin, vitronectin, von Willebrand factor, and laminin.

Collagen is the primary structural protein of the tissues; the reader is referred elsewhere for a focused review on this extensive topic (Fratzl *et al.*, 1998). Many forms of collagen exist, several of which are multimeric and fibrillar. To these collagens many other adhesion proteins bind, thus putting collagen in the role of organizing many other proteins that interact with and organize cells. Collagen also interacts directly with integrins, primarily  $\alpha_1\beta_1$  and  $\alpha_2\beta_1$ .

Fibronectin is a globular protein present in nearly all tissues; fibronectin has been extensively reviewed elsewhere (Magnusson and Mosher, 1998). Fibronectin also exists in many forms, depending on the site in the tissues and the regulatory state of the cell that synthesized the fibronectin. Almost all cells interact with fibronectin, primarily through the so-called fibronectin receptor  $\alpha_5\beta_1$ , and to a lesser extent through the  $\beta_3$  integrin  $\alpha_v\beta_3$  as well as other integrins, as is described later.

Vitronectin is a multifunctional adhesion protein found in the circulation and in many tissues (Preissner and Seiffert, 1998). The protein is active in promoting the adhesion of numerous cell types and binds primarily to the so-called vitronectin receptor,  $\alpha_v\beta_3$ , as well as  $\alpha_v\beta_1$  and to the platelet receptor  $\alpha_{IIb}\beta_3$ .

The von Willebrand factor is an adhesion protein that is involved primarily in the adhesion of vascular cells; the reader is referred elsewhere for a detailed review (Sadler, 1998). It is synthesized by the megakaryocyte, the platelet-generating cells of the bone marrow, and is stored in the  $\alpha$ -granules of circulating platelets. Activation of the platelet leads to the release of the granule contents, including the von Willebrand factor. The von Willebrand factor is also synthesized by and stored within the endothelial cell. A multimeric form of the protein, where tens of copies of the protein may be linked together into insoluble form, is found in the subendothelium and is involved in blood platelet adhesion to the subendothelial tissues on vascular injury.

**Table 21.1.** Selected members of the integrin receptor class and their ligands

<i>Integrin heterodimer</i>	<i>Ligands</i>
$\alpha_1\beta_1$	Collagen, laminin
$\alpha_2\beta_1$	Collagen, laminin
$\alpha_3\beta_1$	Collagen, fibronectin, laminin, thrombospondin-1
$\alpha_4\beta_1$	Fibronectin, osteopontin, vascular cell adhesion molecule-1
$\alpha_5\beta_1$	RGD, fibronectin, L1
$\alpha_6\beta_1$	Laminin
$\alpha_7\beta_1$	Laminin
$\alpha_8\beta_1$	RGD, fibronectin, tenascin
$\alpha_9\beta_1$	Collagen, laminin, osteopontin, tenascin, vascular cell adhesion molecule-1
$\alpha_{10}\beta_1$	Collagen
$\alpha_{11}\beta_1$	Collagen
$\alpha_v\beta_1$	RGD, collagen, fibrinogen, fibronectin, vitronectin, von Willebrand factor
$\alpha_X\beta_2$	Complement protein C3bi, fibrinogen
$\alpha_M\beta_2$	Complement protein C3bi, fibrinogen, intercellular adhesion molecule-1, vascular cell adhesion molecule-1
$\alpha_L\beta_2$	Intercellular adhesion molecule-1 — intercellular adhesion molecule-5
$\alpha_D\beta_2$	Intercellular adhesion molecule-3, vascular cell adhesion molecule-1
$\alpha_v\beta_3$	RGD, bone sialoprotein, fibrinogen, fibronectin, thrombospondin, vitronectin, von Willebrand factor
$\alpha_{IIb}\beta_3$	Fibrinogen, fibronectin, thrombospondin, vitronectin, von Willebrand factor
$\alpha_6\beta_4$	Laminin, hemidesmosomes

Van der Flier and Sonnenberg (2001).

Laminin is a very complex adhesion protein generally present in the basement membrane, the proteins immediately beneath epithelia and endothelia, as well as in many other tissues, as reviewed in detail elsewhere (Miner and Yurchenko, 2004; Sasaki *et al.*, 2004). Laminin is present in a family of forms (Aumailley *et al.*, 2005). The classic form was purified from the extracellular matrix of Engelbreth-Holm-Swarm tumor cells and consists of a disulfide cross-linked trimer of one  $\alpha 1$  (400,000 Da), one  $\beta 1$  (210,000 Da), and one  $\gamma 1$  (200,000 Da) polypeptide chains. This form binds to the  $\beta_1$  integrins  $\alpha_1\beta_1$ ,  $\alpha_2\beta_1$ ,  $\alpha_3\beta_1$ ,  $\alpha_6\beta_1$ , and  $\alpha_7\beta_1$  and to the  $\beta_3$  integrins  $\alpha_v\beta_3$  and  $\alpha_{IIb}\beta_3$ , as well as to other integrins. A number of other laminin forms exist, composed of  $\alpha\beta\gamma$  combinations of  $\alpha 1$ ,  $\alpha 2$ ,  $\alpha 3$ ,  $\alpha 4$ , or  $\alpha 5$ ,  $\beta 1$ ,  $\beta 2$ , or  $\beta 3$ , and  $\gamma 1$  or  $\gamma 2$  chains. The details of the differences in function of all of the various laminin forms remain only partially elucidated, but it is clear that several of them do stimulate very different behaviors in a variety of cell types. Laminin is a particularly important component of the basal lamina, i.e., the extracellular matrix beneath monolayer structures such as epithelia, mesothelia, and endothelia (Schwarzbauer, 1999). For example, laminin contains numerous domains that bind to endothelial cells (Ponce *et al.*, 1999), and these are undoubtedly important in regulating a variety of cell-type-specific functions, as discussed later.

There are several cell morphological hallmarks of integrin binding to adhesion proteins in the extracellular matrix. These include spreading of the cells, extension of cellular membrane processes called *focal contacts* to within approximately 20 nm of the extracellular matrix surface (Shemesh *et al.*, 2005), clustering of integrin receptors at the sites of focal contacts, and assembly of intracellular accessory proteins at the site of clustered integrins to assist in the attachment of the integrin complex to the f-actin cytoskeleton (Ward and Hammer, 1993). These sites of clustered receptors and interaction of the transmembrane receptors with the intracellular cytoskeleton carry most of the stress between the cells and the extracellular matrix or artificial surfaces; indeed, both theoretical analysis and experimental results demonstrate that without the formation of focal contacts and without the connection of numerous transmembrane integrin  $\alpha\beta$  heterodimer complexes into much larger multi-integrin complexes by intracellular proteins such as talin, vinculin, and  $\alpha$ -actinin, cell adhesion would be very much weaker than in reality (Ward and Hammer, 1993). The focal contact serves as an important center for regulation of cell signaling, both mechanically and chemically, as discussed later.

The extracellular matrix proteins just described are very complex. They contain sites responsible for binding to

collagen, for binding to glycosaminoglycans (as described later), for cross-linking to other extracellular matrix proteins via transglutaminase activity, for degradation by proteases (as described briefly later), and for binding to integrin and other adhesion receptors (as described in detail next). Since the proteins must be so multifunctional, the sites that serve the singular function of binding to integrins comprise a small fraction of the protein mass. In most cases, the receptor-binding domain can be localized to an oligopeptide sequence less than 10 amino acid residues in length, and this site can be mimicked by linear or cyclic oligopeptides of identical or similar sequence as that found in the protein (Ruoslahti, 1991). The first such minimal sequence to be identified was the tripeptide RGD (Ruoslahti and Pierschbacher, 1987) (using the single-letter amino acid code, shown in a footnote to Table 21.2). Synthetic RGD-containing peptide, when appropriately coupled to a surface or a carrier molecule (see later), is capable of recapitulating much of the adhesive interactions of the RGD site in the protein fibronectin, including integrin binding. At least for the case of integrin binding via  $\alpha_v\beta_3$ , the RGD ligand alone is capable of also inducing integrin clustering and, when the signal is presented at sufficient surface concentration, focal

contact formation, and cytoskeletal organization (Massia and Hubbell, 1991). Many receptor-binding sequences other than the RGD tripeptide have been identified by a variety of methods, and a few of these sequences are shown in Table 21.2. In these receptor-binding sequences, the affinity is highly specific to the particular ordering of the amino acids in the peptide; for example, the peptide RDG, containing the same amino acids but in a different sequence, is completely inactive in binding to integrins.

One class of the adhesion peptides contains the central RGD sequence. These are modified by their flanking residues, which modify the receptor specificity of the receptor-binding sequence. For example, the sequence found in fibronectin is RGDS, in vitronectin is RGDV, in laminin is RGDN, and in collagen is RGDT. Other adhesion peptides maintain the central D residue, such as the REDV and LDV sequences of fibronectin. The REDV and LDV sequences are relatively specific in their binding and interact with the integrin  $\alpha_4\beta_1$ ; RGD peptides also bind to  $\alpha_4\beta_1$ , but the REDV and LDV sequences bind essentially only to  $\alpha_4\beta_1$ .

In addition to peptides that bind to the integrin adhesion receptors, there are other peptide sequences that bind to other, nonintegrin receptors. As an example, laminin bears several such sequences, such as the YIGSR, SIKVAV, and RNIAEIIKDI peptides. The YIGSR sequence binds to a 67-kDa monomeric nonintegrin laminin receptor (Meecham, 1991). As do the integrin receptors, this laminin receptor also interacts via its cytoplasmic domain with intracellular proteins involved with linkage to the f-actin cytoskeleton. The YIGSR sequence is involved in the adhesion and spreading of numerous cell types (see later). The SIKVAV sequence in laminin binds to a neuronal cell surface receptor and stimulates the extension of neurites (Tashiro *et al.*, 1989).

In addition to the highly sequence-specific binding of adhesion peptides to cell surface receptors, most of the adhesion proteins also bind to cell surface components by less specific mechanisms. These proteins contain a heparin-binding domain (so called because of the use of heparin affinity chromatography in purification of the protein) that binds to cell surface proteoglycans that contain heparan sulfate or chondroitin sulfate glycosaminoglycans (Lyon and Gallagher, 1998). The peptide sequences that bind to cell surface proteoglycans are rich in cationic residues, such as arginine (R) and lysine (K), relative to their content in the anionic residues aspartic acid (D) and glutamic acid (E), and they also contain hydrophobic amino acids, such as alanine (A), isoleucine (I), leucine (L), proline (P), and valine (V). Several of these sequences are shown in Table 21.3. For example, the heparin-binding sequence in fibronectin bears a sequence of PRRARV, having a motif of XBBXB, which is observed in several cell adhesion proteins, X being a hydrophobic residue and B being a basic residue, either K or R. These sites within adhesion proteins such as fibronectin and laminin bind to cell surface proteoglycan in parallel

**Table 21.2.** Selected cell-binding domain sequences of extracellular matrix proteins

Protein	Sequence <sup>a</sup>	Role
Fibronectin	RGDS	Adhesion of most cells, via $\alpha_5\beta_1$
	LDV	Adhesion
	REDV	Adhesion
Vitronectin	RGDV	Adhesion of most cells, via $\alpha_v\beta_3$
Laminin A	LRGDN	Adhesion
	SIKVAV	Neurite extension
Laminin B1	YIGSR	Adhesion of many cells, via 67-kDa laminin receptor
	PDSGR	Adhesion
Laminin B2	RNIAEIIKDI	Neurite extension
Collagen I	RGDT	Adhesion of most cells
	DGEA	Adhesion of platelets, other cells
Thrombospondin	RGD	Adhesion of most cells
	VTXG	Adhesion of platelets

From Hubbell (1995), after Y. Yamada and Kleinman, (1992).  
<sup>a</sup>Single-letter amino acid code: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine.

**Table 21.3.** Proteoglycan-binding domain sequences of extracellular matrix proteins

<sup>a</sup>X indicates a hydrophobic amino acid. Basic amino acids are shown in italics.

with interaction by the integrin-binding sites to stabilize the adhesion complex (Lebaron *et al.*, 1988). Cell–cell adhesion molecules also employ cell surface proteoglycan-binding affinity, e.g., N-CAM bears the domain KHKGRDVILKKDVR, which binds to heparan sulfate and chondroitin sulfate proteoglycans (Kallapur and Akeson, 1992). The interactions with cell surface proteoglycans are much less specific than those with integrins; the binding is not as sensitive to the order of the oligopeptide sequence, and, moreover, the effect can be mimicked simply by R or K residues immobilized on a surface, albeit certainly with a great loss in specificity (Massia and Hubbell, 1992).

The extracellular matrix is subject to dynamic remodeling under the influence of cells in contact with it. Cells seeded *in vitro* on an extracellular matrix of one composition may adhere, spread, form focal contacts, remove the initial protein, secrete a new extracellular matrix of different protein composition, and form new focal contacts. Cell surface-bound and cell-derived free enzymes play an important role in this remodeling of the extracellular matrix (Kleinman *et al.*, 2003). For example, cell-released protein disulfide isomerases are released from cells to a covalently cross-linked protein in the extracellular matrix by disulfide bridging. Cell-derived transglutaminases also form an amide linkage between the  $\epsilon$ -amino group of lysine and the side group amide of glutamine to chemically cross-linked proteins in the extracellular matrix. These processes are responsible, for example, for the assembly of the globular adhesion protein fibronectin into fibrils within the extracellular matrix beneath cells.

Membrane-bound and cell-released enzymes are also involved in degradation of the extracellular matrix to permit matrix remodeling and cell migration (Shapiro, 1998). Cell-released matrix metalloproteinases such as collagenase and gelatinase, serine proteases such as urokinase plasminogen activator and plasmin, and cathepsins are each involved in both remodeling and degradation during cell migration. Accordingly, the matrix–cell interaction

should be understood to be bidirectional: the cell accepting information from the matrix, and the matrix being tailored by the cell.

One of the important roles of cell-associated enzymatic degradation of the extracellular matrix is in mobilization of growth factor activity. Because growth factors are such powerful regulators of biological function, their activity must be highly spatially regulated. One means by which this occurs in nature is by high-affinity-binding interactions between growth factors and the three-dimensional extracellular matrix in which they exist. Many such growth factors bind heparin, meaning that they, like adhesion proteins, bear domains that bind extracellular matrix heparan sulfate and chondroitin sulfate proteoglycans. For example, basic fibroblast growth factor binds heparin with high affinity (Faham *et al.*, 1998). Vascular endothelial growth factor is another example of a heparin-binding growth factor (Fairbrother *et al.*, 1998). These growth factors are strongly immobilized by binding to extracellular matrix proteoglycans, and they can be mobilized under local cellular activity, e.g., by degradation of these proteoglycans or, in the case of vascular endothelial cell growth factor, by cleavage of the main chain of the growth factor away from the heparin-binding domain by plasmin activated at the surface of a nearby cell. Fundamental studies have demonstrated that the interaction between growth factors and the extracellular matrix can dramatically alter their local behavior, where the length scale of the local response is measured in single cell diameters. Specifically, very low interstitial flows can convect cell-derived proteases directionally downstream of a cell, and these proteases can liberate matrix-bound growth factors that were previously homogeneously distributed throughout the matrix. Since the protease activity is preferentially downstream of the cell, growth factor liberation is also pre-ferentially downstream. This can create gradients of growth factor, allowing the cell to sense the directionality of flow, even when the flows are extremely subtle (Helm *et al.*, 2005; Fleury *et al.*, 2006).

### III. MODEL SYSTEMS FOR STUDY OF MATRIX INTERACTIONS

Since the extracellular matrix adhesion proteins may be mimicked, at least to some degree, by small synthetic peptides, it is possible to investigate cell–substrate interactions with well-defined systems. Foundational to them all are the interactions of cells with the surface, other than with adhesion peptides intentionally endowed on the surface, that would produce cell adhesion. These so-called nonspecific interactions are between cell surface receptors and proteins that have adsorbed to the surface. Due to this role played by adsorbing proteins, some introduction to the protein and surface interactions leading to adsorption is warranted. The thermodynamic and kinetic aspects of protein adsorption have been reviewed and the reader is

referred elsewhere for a more detailed treatment (Andrade and Hlady, 1986). The primary driving force for protein adsorption is the hydrophobic effect: Water near a hydrophobic material surface fails to hydrogen bond with that surface and thus assumes a more highly ordered structure in which the water is more thoroughly hydrogen bonded to itself than is the case in water far away from the surface. A protein can adsorb to this surface, acting like a surfactant, and thus replace the hydrophobic material surface with a polar surface capable of hydrogen bonding with water. This releases the order in the water, with a net result of a large entropic gain. Electrostatic interactions, e.g., between charges on D, E, K, or R residues on the protein with cationic or anionic functions on the material surface, play a lesser but important role as well; since proteins generally bear a net negative charge, anionic surfaces typically adsorb less protein than do cationic surfaces. These observations, overly generalized in the preceding sentences, guide one to examine model surfaces that are hydrophilic and nonionic as well as being derivatizable to permit coupling of the adhesion peptide under study.

The tendency for proteins to adsorb to material surfaces has been exploited as a method by which to immobilize peptides onto substrates for study. Pierschbacher *et al.* have described the peptide Ac-GRGDSPASSKGGGSRLLLLL-NH<sub>2</sub> (where the Ac indicates that the N-terminus is acetylated and the -NH<sub>2</sub> indicates that the C-terminus is amidated to block the terminal charges) for this purpose (Ruoslahti and Pierschbacher, 1986). The LLLLLL stretch is hydrophobic and adsorbs avidly to hydrophobic polymer surfaces and effectively immobilizes the cell-binding RGDS sequence from fibronectin. Nonadhesive proteins such as albumin have also been grafted with RGD peptide, e.g., by binding to amine groups on lysine residues on the albumin; adsorption of the albumin conjugate thus immobilizes the attached RGD peptide (Danilov and Juliano, 1989).

Surfaces coated with hydrophilic polymers have also been employed to graft adhesion peptides. One simple system that has been useful is glass modified with a silane, 3-glycidioxypropyl triethoxysilane; once the silane is grafted to the surface, the epoxide group is hydrolyzed to produce -CH<sub>2</sub>CH(OH)CH<sub>2</sub>OH groups pendant from the surface (glycophase glass). The hydroxyl groups serve as sites for covalent immobilization of adhesion peptide, e.g., via the N-terminal primary amine (Massia and Hubbell, 1990). Titration of the surface density of grafted RGD peptides versus cell response using this system revealed quantitative information on the number density of interactions required to establish morphologically complete cell spreading (Massia and Hubbell, 1991). A surface density of approximately 10 fmol/cm<sup>2</sup> of RGD was required to induce spreading, focal contact formation, integrin  $\alpha_v\beta_3$  clustering,  $\alpha$ -actinin and vinculin colocalization with  $\alpha_v\beta_3$ , and f-actin cytoskeletal assembly in human fibroblasts cultured on this synthetic extracellular matrix. This surface density corre-

sponds to a spacing of roughly 140 nm between immobilized RGD sites, demonstrating that far less than monolayer coverage is sufficient to promote cell responses. Silane-modified quartz has been employed as a surface to study the role of RGD sites and heparin-binding domains of adhesion proteins in osteoblast adhesion and mineralization, demonstrating a strong benefit for the involvement of both modes of adhesion (Rezania and Healy, 1999). The base material, glycophase glass, is only modestly resistant to protein adsorption and thus to nonspecific cell adhesion; accordingly, the investigation of long-term interactions, during which the adherent cells may be synthesizing and secreting their own extracellular matrix to adsorb to the synthetic one experimentally provided, are difficult to investigate. This has motivated exploration with substrates that are more resistant to protein adsorption.

An enormous amount of research has been expended into grafting material surfaces with water-soluble, nonionic polymers such as polyethylene glycol, HO(CH<sub>2</sub>CH<sub>2</sub>O)<sub>n</sub>H, abbreviated PEG. This vast body of research has been extensively reviewed elsewhere (Otsuka *et al.*, 2003). Polyethylene glycol has been immobilized on surfaces by numerous means; three particularly effective means are addressed in the following paragraphs.

Thiol compounds bind by chemisorption avidly to gold surfaces (Love *et al.*, 2005; Whitesides *et al.*, 2005). When those thiols are terminal to an alkane group, R-(CH<sub>2</sub>)<sub>n</sub>-SH, the thiol adsorbs in perfect self-assembling monolayers; the thiol-gold interaction contributes about half of the energy of interaction, and the alkane-alkane van der Waals interaction contributes the other half. Accordingly, it is easy to employ alkanethiols to display, in very regular fashion, some functionality R on a gold-coated substrate (so long as the R group is not so large as to sterically inhibit monolayer packing, in which case it can be diluted with a nonfunctional alkanethiol). Using this approach, Prime and Whitesides (1993) immobilized oligoethylene glycol-containing alkanethiol, HS-(CH<sub>2</sub>)<sub>11</sub>(OCH<sub>2</sub>CH<sub>2</sub>)<sub>n</sub>OH, on gold surfaces. Protein adsorption was investigated on surfaces formed with this alkanethiol and a hydrophobic coreactant, HS-(CH<sub>2</sub>)<sub>10</sub>CH<sub>3</sub>. Degrees of polymerization (*n*) as low as 4 were observed to dramatically limit the adsorption of even very large proteins, such as fibronectin. When the oligoethylene glycol monolayer was incomplete, i.e., when the monolayer was mixed with the hydrophobic alkanethiol, longer oligoethylene glycol functions were able to preserve the protein repulsiveness of the surface. Since the background amount of protein adsorption on these materials is so low, one would expect them to be very useful as substrates for peptide attachment for studies with model synthetic extracellular matrices, e.g., with HS-(CH<sub>2</sub>)<sub>11</sub>(OCH<sub>2</sub>CH<sub>2</sub>)<sub>n</sub>-NH-RGDS.

Drumheller and Hubbell have developed a polymeric material that was highly resistant to cell adhesion for use in peptide grafting (Drumheller and Hubbell, 1994;

Drumheller *et al.*, 1994). Materials that contain large amounts of polyethylene glycol generally swell extensively, rendering material properties sometimes unsuitable for cell culture or medical devices. To circumvent this, the polyethylene glycol swelling was constrained by distributing it as a network throughout a densely cross-linked network of a hydrophobic monomer, trimethylolpropane triacrylate. This yielded a material with the surface hydrophilicity of a hydrogel but with mechanical and optical properties of a glass. These materials were highly resistant to protein adsorption, even after an adsorptive challenge to the material with a very large adhesion protein, laminin, and even over multiweek durations. When the polymer network was formed with small amounts of acrylic acid as a comonomer, the polymer still remained cell nonadhesive. The carboxyl groups near the polymer surface were useful, however, as sites for derivatization with adhesion peptides such as the RGD and YIGSR sequences. Since the adsorption of proteins to those surfaces was so low, materials endowed with inactive peptides such as the RDG supported no cell adhesion.

Numerous other approaches are possible. One of particular interest, because of its ease of use, is physisorption. Block copolymers, consisting of adsorbing domains and nonadsorbing domains, can be adsorbed to material surfaces and can be used to regulate biological interactions. For example, when the nonadsorbing domains are polyethylene glycol, surfaces can be generated that display very low levels of nonspecific adhesion (Amiji and Park, 1992). One convenient class of polymers are ABA block copolymers of polyethylene glycol (the A blocks) and polypropylene glycol (B), in which the hydrophilic and cell-repelling polyethylene glycol domains flank the central hydrophobic and adsorbing polypropylene glycol block. The central hydrophobic block adsorbs well to hydrophobic surfaces, thus immobilizing the hydrophilic polymer and thereby resisting cell adhesion (Amiji and Park, 1992). Cell adhesion peptides can be displayed at the tips of these hydrophilic chain termini, and a very effective and simple model surface can be obtained (Neff *et al.*, 1998, 1999). Similar constructions can be designed for anionic surfaces, e.g., by using a polycationic block as a binding domain, with polyethylene glycol chains attached thereto (Elbert and Hubbell, 1998; Kenausis *et al.*, 2000; Huang *et al.*, 2001). Adhesion-promoting peptides may be grafted to the termini of the dangling polyethylene glycol chains, to permit cell attraction to these ligands on an otherwise remarkably nonadhesive background (VandeVondele *et al.*, 2003).

Model systems have also been employed for ligand discovery, i.e., to determine which parts of an adhesion protein are responsible for binding to an adhesion receptor. This has been most convincingly implemented using peptide arrays, i.e., surfaces in which peptides have been immobilized or even more powerfully synthesized in small domains on an otherwise-passive substrate (Mrksich, 2002; Min and Mrksich, 2004). Arrays of peptides that constitute overlap-

ping sequences order of 10 amino acids long spanning the entire length of a candidate adhesion protein can be constructed. If a receptor for the putative binding site is already known, it can be labeled, e.g., with a fluor, and the identity of peptides that bind can be determined by the location of the spots that bind the fluorescent protein. If a candidate receptor is not known, then larger spots can be synthesized (which somewhat limits the size of the peptide library that is formed), and the identity of adhesion-promoting peptides can be determined by the location of spots that promote cell adhesion and spreading, for example. Once the identity of a binding peptide is determined, the binding receptor can be determined by affinity chromatography of cell-derived proteins on columns containing bound peptide, with proteomic analysis of the protein that bind.

The aforementioned model systems for the study of cell-matrix interactions are all two-dimensional systems. Three-dimensional systems have also been developed in an effort to mimic the spatial complexity of the natural extracellular matrix (Lutolf and Hubbell, 2005; Pedersen and Swartz, 2005; Griffith and Swartz, 2006). Some of these utilize natural proteins, such as cell-derived extracellular matrix, fibrin, and collagen (Helm *et al.*, 2005; Mao and Schwarzbauer, 2005; Ng and Swartz, 2006). Some systems enable the identity and amounts of adhesion ligands, and potentially other ligands, to be precisely controlled. Two approaches are presented in the following paragraphs by way of example.

When fibrin forms spontaneously, nonfibrin proteins, such as fibronectin, are grafted into the nascent fibrin network by the enzymatic activity of the coagulation transglutaminase factor XIIIa. This feature of coagulation has been exploited to engineer fibrin matrices, by coagulating fibrinogen in the presence of exogenous and even synthetic factor XIIIa substrates (Schense and Hubbell, 1999). For example, if an adhesion ligand is synthesized as a fusion with a factor XIIIa substrate peptide, the adhesion ligand will be immobilized within the fibrin network. This approach has been carried out with small synthetic adhesion peptides (Schense *et al.*, 2000), with recombinant proteins that are fusions with a factor XIIIa substrate domain (Hall and Hubbell, 2004), and with peptides that bind glycosaminoglycans, which can in turn bind to growth factors (Sakiyama-Elbert and Hubbell, 2000). One can incorporate other bioactive molecules, such as growth factors, directly within the fibrin matrices, also by expressing them as recombinant fusion proteins with factor XIIIa substrate domains (Ehrbar *et al.*, 2004). Using these approaches, three-dimensional matrices for cell culture investigations of basic cellular processes can be constructed.

Synthetic three-dimensional matrices that allow precise control of cell adhesion ligand display have also been developed. In one system, reactively functionalized branched polyethylene glycol is cross-linked by a counterreactive peptide, the peptide being designed with a sequence that is

a substrate for proteases that cells use when they migrate, such as matrix metalloproteinases or plasmin (Lutolf *et al.*, 2003). To the ends of some of the polyethylene glycol arms are also grafted adhesion ligands, such as a reactive RGD peptide. Although the porosity of these hydrogels is very small compared to the length scale of the smallest of processes that cells extend when they migrate, local activation of proteases at the cell membrane surface enables the cells to proteolytically tunnel their way through the materials (Raeber *et al.*, 2005). Like the fibrin materials described earlier, these materials are useful both as model systems for study of cell biology as well as for therapeutic ends.

#### IV. CELL PATTERN FORMATION BY SUBSTRATE PATTERNING

The ability to control material surface properties precisely enables the formation of designed architectures of multiple cells in culture and potentially *in vivo* as well. Large-scale architectures have been formed by patterning adhesive surfaces. Four methods for patterning have been particularly powerful: photolithography, mechanical stamping, microfluidics, and lift-off.

Photolithographic methods have been employed to impart patterns on cell adhesion surfaces. Alkoxysilanes have been chemisorbed to glass surfaces (using the same grafting chemistry as with the glycophasic glass described earlier), and ultraviolet light was employed to selectively degrade the alkoxy group to yield patterns of surface hydroxyl groups (Healy *et al.*, 1994). These hydroxyl groups were used as sites for reaction with a second layer of an amine-containing alkoxysilane. These aminated regions supported cell adhesion and thus formed the cell-binding regions on the patterned substrate (Kleinfeld *et al.*, 1988). Patterned amines on polymer surfaces have also been employed to induce cell patterning via adhesive domains patterned on a nonadhesive background (Ranieri *et al.*, 1993). These approaches have been combined with the bioactive peptide technology described earlier. For example, patterned amines have been used as grafting sites for the adhesive peptide YIGSR to pattern neurite extension on material surfaces (Ranieri *et al.*, 1994). One of the goals of this work was to create neuronal networks as a simple system in which to study communication among networks of neurons. A powerful system for such work has been provided by using adhesive aminoalkylsilanes patterned on a nonadhesive perfluoroalkylsilane background (Stenger *et al.*, 1992). Polymers have been synthesized explicitly for the purpose of attaching adhesive peptide sequences such as RGD, and these will be very useful in future studies of cell–cell interactions in neuronal and other cell systems (Herbert *et al.*, 1997). Such patterned surfaces have been formed to control cell shape and size, in order to gain deeper insight into the interplay between cell biomechanics and cell function (Thomas *et al.*, 1999). It is particularly

convenient in photopatterning studies to develop photochemistries on materials specifically for the purpose of immobilizing polymers and polymer-peptide adducts (Moghaddam and Matsuda, 1993); this has been addressed, e.g., with phenylazido-derivatized surfaces (Matsuda and Sugawara, 1996; Sugawara and Matsuda, 1996).

Alkanethiols on gold have also been patterned using simple methods. Contact printing has been employed for this purpose (Love *et al.*, 2005; Whitesides *et al.*, 2005). Conventional photolithographic etching of silicon was employed to make a master printing stamp, a negative of which was then formed in silicone rubber. Structures as small as 200 nm were preserved in the silicone rubber stamp. The stamp was then wetted with a cell adhesion-promoting alkanethiol  $\text{HS}-(\text{CH}_2)_{15}-\text{CH}_3$ . Stamping a gold substrate resulted in creation of a pattern of the hydrophobic alkane group. The stamped gold substrate was then treated with the cell-resistant alkanethiol  $\text{HS}-(\text{CH}_2)_{11}(\text{OCH}_2\text{CH}_2)_6\text{OH}$ . Using this system it was possible to create adhesive patches of defined size on a very cell nonadhesive substrate (Singhvi *et al.*, 1994). Microcontact printing can also be employed with binding approaches other than alkane thiols binding to gold. For example, adhesion proteins such as laminin have been stamped onto reactive silane-modified surfaces to produce patterns to guide neurite outgrowth in culture (Wheeler *et al.*, 1999). This very flexible and powerful system will be useful in a wide variety of cell biological and tissue-engineering applications.

A third powerful method is based on microfluidic systems, in which silicone rubber stamps are formed with silicon masters; the stamps are pressed to a surface, and the thin spaces patterned thereby are employed as capillaries to draw up fluid, containing a treatment compound, onto desired regions of the surface. The fluid can contain a soluble, adsorbing polymer with an attached adhesion peptide (Neff *et al.*, 1998), or it can contain a peptide with some affinity linker for the surface. In the practice of the latter, it is powerful to employ the very high-affinity streptavidin–biotin pair, e.g., by biotinylating the polymer at the surface and exposing, with the aid of the microfluidics channels, to peptide conjugated to streptavidin (Patel *et al.*, 1998).

In a fourth method, also involving silicone layers on material surfaces, silicone layers can be used to pattern directly the locations in which cells adhere to surfaces, and the silicone layers can be lifted off the substrate, if desired, after such cell attachment (Sniadecki *et al.*, 2006). Using such approaches, it is possible to pattern two-dimensional surfaces as well as three-dimensional microwells atop such two-dimensional surfaces.

#### V. CONCLUSIONS

While it is tempting to think of the matrix to which cells attach as providing primarily a mechanical support, it is clear from the preceding text that this is only a small part of

the picture. Cell interaction with adhesive substrates is known to provide signaling information to the cells via numerous means, both biochemical and biomechanical, and this topic has been extensively reviewed (Roskelley *et al.*, 1995; Katz and Yamada, 1997; Otoole, 1997; K. M. Yamada, 1997; Danen *et al.*, 1998; Discher *et al.*, 2005; Pedersen and Swartz, 2005; Griffith and Swartz, 2006). The biochemical mechanisms underlying these interactions are likely numerous and have not yet been fully elucidated. One key mechanism involves the focal contact as a site for catalysis. Integrin clustering induces tyrosine phosphorylation of several proteins, many of which still have unknown function (Cohen and Guan, 2005). One of these proteins is a 125-kDa tyrosine kinase that localizes, after it is tyrosine phosphorylated, at the sites of focal contacts; this protein has been accordingly named pp125 focal adhesion kinase, or pp125<sup>fa</sup>. Thus, although the cytoplasmic domain of integrins bears no direct catalytic activity, clustering of integrins is known to stimulate tyrosine phosphorylation, and further specific kinases are known to assemble at the sites of clustered integrins. Interestingly, when cells were permitted to spread via a non-integrin-mediated mechanism, specifically by interaction of cell surface proteoglycans with surface-adsorbed polycations, phosphorylation of intracellular proteins did not occur (Cohen and Guan, 2005). The phosphorylation of these proteins, associated with focal contact formation, is known to be an important signal for survival of a variety of cell types (Frisch *et al.*, 1996). Thus, the matrix plays not only a mechanical role as a support for cell adhesion and migration, but also a key signaling role in determining the details of cell behavior, ranging from survival to differentiation.

Engineered biomaterials will play an increasingly important role in deciphering the language of the interac-

tion between cells and their extracellular matrix (Lutolf and Hubbell, 2005). Indeed, this represents one of the key challenges for researchers as the field moves forward, to represent more faithfully the complexity of the natural extracellular matrix in synthetic analogs. It is clear that the complex cellular interactions that exist with the three-dimensional milieu *in vivo* cannot be represented well by culture of cells on simple two-dimensional substrates like cell culture flasks (Griffith and Swartz, 2006), and it falls to the tissue engineer to develop more physiologically representative models.

While one goal of biomaterials and tissue-engineering research is certainly to develop systems for the quantitative study of biological interactions, another is to develop practical novel therapeutics. Many of the concepts described herein, both in terms of development of model surfaces and especially three-dimensional matrices and with regard to manipulating cellular behavior, are directly transferable; however, some cautionary comments should be made. It is not only the chemical identity of an adhesion peptide that determines its biological activity, but also its amount and distribution. This was very clearly demonstrated by Palecek *et al.* (1997), who showed that small amounts of an adhesion molecule could enhance cell migration, whereas larger amounts could inhibit it. They further demonstrated that this effect depended on, among other features, the affinity of the receptor-ligand pair, the number of receptors, and the polarization of receptors from the leading to the trailing edge of the cell. Given that many of these features depend on the state of the cell and can be modulated by the cell's biological environment, e.g., by the growth factors to which the cell is exposed (Maheshwari *et al.*, 1999), many confounding features must be considered in translation from model to practical application (Lutolf and Hubbell, 2005).

### I. INTRODUCTION

In the modern age of medicine, tissue engineering has become a viable option for the replacement of tissue and organ function. The creation of such substitutes requires a three-dimensional, porous, biocompatible, and preferably biodegradable scaffold. Tissue-engineering scaffolds should have geometries that direct new tissue formation and mass transport properties sufficient for the exchange of biological nutrients and waste. The scaffolds also provide temporary mechanical support to the regenerating tissue. They must degrade into biocompatible byproducts, ideally on a time scale comparable to that of new tissue development. Such scaffolds are typically fabricated with biocompatible polymers, proteins, peptides, and inorganic materials. Aside from the properties of the raw material, the major factor determining the final scaffold characteristics is the fabrication technique utilized to produce the scaffold. Mechanical strength, porosity, degradation rates, surface chemistry, and the ability to incorporate biologically active molecules are all aspects affected by the manner of fabrication. This chapter discusses many established processing and fabrication methods using various polymeric components, including fiber bonding, electrostatic fiber spinning, solvent

casting and particulate leaching, melt molding, membrane lamination, extrusion, freeze-drying, phase separation, high-internal-phase emulsion, gas foaming, polymer/ceramic composite fabrication, rapid prototyping, peptide self-assembly, and *in situ* polymerization.

In an era of decreasing availability of organs for transplantation and a growing need for suitable replacements, the emerging field of tissue engineering gives hope to patients who desperately require tissue and organ substitutes. Scaffolding is essential in this endeavor to act as a three-dimensional template for tissue ingrowth by mimicking the extracellular matrix (ECM) for cell adhesion and proliferation (Freed *et al.*, 1994). Since the mid-1980s, researchers have developed many novel techniques to shape polymers into complex architectures that exhibit the desired properties for specific tissue-engineering applications. These fabrication techniques result in reproducible scaffolds for the regeneration of specific tissues. Polymer scaffolds can provide mechanical strength, interconnected porosity and surface area, varying surface chemistry, and unique geometries to direct tissue regeneration (Hutmacher, 2001). These key scaffold characteristics can be tailored to

the application by careful selection of the polymers, additional scaffold components, and the fabrication technique.

Patient safety is the paramount concern for any tissue-engineering application. The bulk material and degradation products of the scaffold must be biocompatible and clearable by the body. It is equally critical that the elected processing strategy not affect the biocompatibility and biodegradability of the scaffolding materials. Restoring the function of a tissue or replacing an organ entirely requires a porous scaffold that degrades on an appropriate time scale so that the new tissue replaces the resorbing scaffold. The primary function of the scaffold is to direct the growth and migration of cells from surrounding tissues into the defect or to facilitate the growth of cells seeded into the scaffold prior to implantation. Surface chemistry favorable to cell attachment and proliferation is desirable. Large pore diameters and high pore interconnectivity are essential for confluent tissue formation, transport of nutrients and metabolic wastes, and sufficient vascularization of the new tissue. Increased porosity and pore diameter can result in increased surface-area-to-volume ratios within the scaffold or more surfaces for cell adhesion. Control over the scaffold's size and shape provides increased utility for differing tissue-engineering applications.

The mechanical properties of a scaffold arise from a combination of the properties of the bulk polymer, the geometry of the scaffold, incorporation of strength-enhancing materials, and the scaffold fabrication technique. For example, polymers with higher crystallinity exhibit increased tensile strength at the expense of slower degradation rates. Processing methods that reduce crystallinity or the molecular weight of polymer chains diminish the strength of the scaffold and reduce the scaffold's lifetime. Elevated mechanical strength is preferable in the regeneration of load-bearing tissues such as bone and cartilage. Mechanical stimulation via force transduction can be beneficial in the differentiation of many cell types (Tan *et al.*, 1996). While hydrophobic polymers typically offer greater mechanical properties, adsorbing proteins may become denatured through interaction with the surface (Gray, 2004). Typical materials utilized in tissue engineering scaffolds include synthetic polymers [e.g., poly(glycolic acid) (PGA), poly(L-lactic acid) (PLLA), poly(D,L-lactic-co-glycolic acid) (PLGA) copolymers, poly( $\epsilon$ -caprolactone) (PCL), and ethylene glycol-based copolymers], natural polymers (e.g., collagens, gelatins, fibrin, carbohydrates, peptides, and nucleic acids), and inorganic materials (e.g., hydroxyapatite, tricalcium phosphate, and titanium).

The inclusion of bioactive molecules is another major consideration in the design of porous scaffolds. Bioactive molecules include proteins, ECM-like peptides, and DNA. Because the bioactive molecules are incorporated for cell adhesion, cell signaling, or drug/gene delivery, fabrication techniques that do not inactivate the molecules must be utilized. Local drug and gene delivery to promote cell

migration, proliferation, and differentiation is an enormous tool to improve the required time and quality of tissue regeneration (Jang *et al.*, 2004).

The fabrication technique for tissue-engineering scaffolds depends almost entirely on the bulk and surface properties of the material and the proposed function of the scaffold. However, the cost and time of manufacturing scaffolds must be considered for the viability of patient treatment. Most techniques involve the application of heat and/or pressure to the polymer or dissolving it in an organic solvent to mold the material into its desired shape. Evolving techniques have been studied that reduce potentially harsh conditions of older scaffold fabrication schemes to protect incorporated cells and bioactive molecules. While each method presents distinct advantages and disadvantages, the appropriate technique must be selected to meet the requirements for the specific type of tissue.

## II. FIBER BONDING

Polymer fibers exhibit an excellent surface-area-to-volume ratio for enhanced cell attachment, making them a viable option as a scaffold material. The earliest tissue-engineering scaffolds were fiber mesh, nonbonded PGA tassels or felts that lacked the mechanical integrity to be used for *in vivo* organ regeneration (Cima *et al.*, 1991). To overcome this problem, fiber-bonding techniques were developed to bind the fibers together at points of intersection. The original examples of fiber-bonded scaffolds used PGA and PLLA polymers (Mikos *et al.*, 1993a). Briefly, PGA fibers are arranged in a nonwoven mesh. At temperatures above the melting point of the polymer, the fibers will bond at their contact points. To prevent a structural collapse of the melting polymer, PGA fibers are encapsulated prior to heat treatment. PLLA, dissolved in methylene chloride (not a solvent for PGA), is cast over the meshed fibers and dried, resulting in a PGA–PLLA composite matrix. After heat treatment and fiber bonding, the PLLA is dissolved in methylene chloride and the solvent is removed from the scaffold by vacuum drying. Another method involves rotating a nonwoven PGA fiber mesh while spraying it with an atomized PLLA or PLGA solution (Mooney *et al.*, 1996a). The polymer solution builds up on the PGA fibers and bonds them at contact points. This method provides the mechanical properties of PGA while exposing cells to the surface properties of PLLA or PLGA. This method is excellent for producing tubular structures, but it lacks the ability to create complex three-dimensional structures and increases the original fiber diameter. Similar methods exist for other biocompatible polymer fibers.

The fiber-bonding scaffold fabrication technique is desirable for its simplicity, the retention of the PGA fibers' original properties, the use of only biocompatible materials, and the structural advantages over tassel or felt arrangements. The drawbacks of fiber bonding are the lack of control over porosity and pore size, the availability of suit-

able solvents, immiscibility of the two polymers in the melt state, and the required relative melting temperatures of the polymers.

### III. ELECTROSPINNING

A modern method for creating porous scaffolds composed of nano- and microscale biodegradable fibers employs electrostatic fiber spinning, or electrospinning, a technology derived from the electrostatic spraying of polymer coatings. Electrospinning fabricates highly porous scaffolds of nonwoven and ultrafine fibers. Many biocompatible polymers, including PGA, PLGA, and PCL, can be electrospun into scaffolds of nanofibers with porosities greater than 90% (Yoshimoto *et al.*, 2003). Scaffolds are prepared by dissolving the selected polymer in an appropriate solvent (e.g., PCL in chloroform). The polymer solution is loaded into a syringe and then expelled through a metal capillary at a constant rate via syringe pump. A high voltage (10–15 kV) is applied to the capillary, charging the polymer and ejecting it toward a grounded collecting surface. As the thin fibers assemble on the plate, the solvent evaporates, leaving a nonwoven porous scaffold. Fiber thickness, scaffold diameter, and average pore diameter are adjusted by factors including polymer concentration, choice of solvent, ejection rate, applied voltage, capillary diameter, collecting plate material, and the distance between the capillary and the collecting plate. Examples of electrospun P(LLA-CL) fiber meshes are shown in Fig. 22.1. Electrospun scaffolds exhibit promise

in mesenchymal stem cell culture for bone and cartilage tissue engineering (Pham *et al.*, 2006).

### IV. SOLVENT CASTING AND PARTICULATE LEACHING

For enhanced control over porosity and pore diameter as compared to most fabrication methods, a solvent-casting and particulate-leaching technique was developed. With careful system selection, porous scaffolds can be manufactured with specific pore size, porosity, surface-area-to-volume ratio, and crystallinity. This technique involves casting a dissolved polymer around a suitable porogen, drying and solidifying the polymer, and leaching out the porogen to yield a polymer scaffold with an interconnected porous network. Early systems utilized PLLA and PLGA polymers with sieved salt particles as a porogen (Mikos *et al.*, 1994). To adjust the crystallinity, the composite material is heated above the polymer melting temperature and annealed at the appropriate rate prior to porogen leaching. Afterwards, the composite is immersed in water to remove the salt particles, leaving a porous PLLA membrane. Similar techniques have utilized alternative biocompatible porogens, such as sugars (Holy *et al.*, 1999) and lipids (Hacker *et al.*, 2003). A solvent exchange system, where the second organic phase dissolves the porogen but is a nonsolvent for the polymer, eliminates the traditional leaching step and presents an advantage in the total leaching time required.

**FIG. 22.1.** Scanning electron micrographs of P(LLA-CL) fibers electrospun at an applied voltage of 12 kV from different polymer concentration solutions: (A) 3 wt%; (B) 5 wt%; (C) 7 wt%; (D) 9 wt%. Reprinted from X. M. Mo, C. Y. Xu, M. Kotaki, and S. Ramakrishna (2004), Electrospun P(LLA-CL) nanofiber: a biomimetic extracellular matrix for smooth muscle cell and endothelial cell proliferation, *Biomaterials* **25**, pp. 1883–1890. Copyright 2003, with permission of Elsevier Science.

For polymers preloaded with bioactive molecules, salt leaching can remove molecules or decrease their bioactivity during the leaching process.

This technique can produce scaffolds with controlled porosity (up to 93%), pore size (up to 500  $\mu\text{m}$ ), and crystallinity. By adjusting the fabrication parameters and the type, amount, and size of porogen, porous scaffolds can be tailored to the tissue-engineering application of interest. The primary advantage to this technique is the relatively small amount of polymer required to create a scaffold. PLGA and poly(ethylene glycol) (PEG) blends have been utilized to produce porous foams with the solvent casting and particulate leaching technique that are less brittle and more suitable for soft-tissue regeneration (Wake *et al.*, 1996). To overcome problems with cell seeding due to the polymer's hydrophobicity, scaffolds can be prewetted using ethanol (Mikos *et al.*, 1994). The scaffolds are submerged first in ethanol, followed by water. Prewet scaffolds show higher cell attachment for chondrocytes and hepatocytes. As an alternative, PLGA scaffolds have been soaked and coated with more hydrophilic polymers, such as poly(vinyl alcohol) (PVA) (Mooney *et al.*, 1994). The attachment of hepatocytes was greatly increased for PVA-coated scaffolds as compared to untreated PLGA scaffolds.

## V. MELT MOLDING

An alternative method for the production of three-dimensional scaffolds is melt molding. This technique calls for polymer and porogen particles to be combined in a mold and heated above the polymer's glass transition temperature (for amorphous polymers) or melting temperature (for semicrystalline polymers). After the reorganization of the polymer, the composite material is removed from the mold, cooled, and soaked in an appropriate liquid to leach out the porogen. The resulting porous scaffold has the exact external shape as the mold. PLGA/gelatin microparticle composites have been formed in this fashion with gelatin leaching in distilled-deionized water (Thomson *et al.*, 1995a). Melt molding allows for the formation of scaffolds of any desired geometry by altering the size and shape of the mold. Adjusting the amount and size of porogen used, respectively, can control the porosity and pore size of the scaffold. The melt-molding protocol can be adapted to incorporate materials such as hydroxyapatite fibers (Thomson *et al.*, 1995b). Such fibers provide additional mechanical support and a bioactive surface for cells when uniformly distributed throughout the polymer prior to melting. Melt molding is advantageous for the inclusion and delivery of bioactive molecules because the materials are not exposed to harsh organic solvents, although excessively high molding temperatures can degrade and inactivate the molecules.

## VI. MEMBRANE LAMINATION

Tissue engineering often requires precise three-dimensional anatomical geometries for hard tissues with shape-dependent function like bone and cartilage. Thin

layers of porous polymer produced in the previously mentioned manners can be cut, stacked, and bonded by means of membrane lamination (Mikos *et al.*, 1993b). The layers are chemically joined, but there is no distinguishable boundary at the interface of two adjacent membranes. The key to this method is the creation of a three-dimensional contour plot of the desired scaffold shape. Each layer of the scaffold is cut from a highly porous membrane into its corresponding shape for that level. A small amount of solvent, such as chloroform, is coated on the interfacial surface, and a bond is formed between membranes. This process is repeated for all subsequent layers until the completion of the final three-dimensional structure.

Porous polymers used in membrane lamination include PLLA and PLGA membranes formed by solvent casting and particulate leaching. As previously mentioned, there is no detectable boundary between layers in the finished scaffold. Membrane lamination provides a method for fabricating three-dimensional anatomical shapes with identical bulk properties to the individual membranes. Membrane lamination has also been utilized in the preparation of degradable tubular stents (Mooney *et al.*, 1994). Porous membranes of PLGA are produced by solvent casting and particulate leaching and wrapped around a Teflon cylinder. The overlapped edges are bonded with a small volume of solvent, and the Teflon is removed, yielding a hollow cylinder of porous PLGA for applications such as intestinal and vascular regeneration.

## VII. EXTRUSION

While extrusion is a well-documented processing method for industrial polymers such as polyethylene, this method is relatively new for biocompatible porous scaffold production. The first extrusion of polymers for tissue engineering utilized PLGA and PLLA to form tubular scaffolds for peripheral nerve regeneration (Widmer *et al.*, 1998). Extruded tubular PLGA scaffolds are illustrated in Fig. 22.2. The polymers were fabricated into membranes using solvent casting, with sodium chloride as a porogen. The membranes were cut to appropriate sizes and loaded into a customized extrusion tool. The extruder applies heat and pressure to the composite material and forces it through a die and out the nozzle to form cylindrical conduits. After the conduits are cooled, they are soaked in water, to leach the salt, and vacuum dried. Higher temperatures require less pressure, and vice versa. While high pressures may require a powerful hydraulic press, high temperatures can adversely affect the crystallinity and porosity of the scaffold and the activity of incorporated biomolecules. As with other methods, porogen content and size are the most important parameters of porosity and average pore diameter. Extruded polymer scaffolds can be fabricated to support the loading of cells or growth factors for tissue engineering. PLGA, PCL, and most biocompatible polymers can be extruded at appropriate temperatures and pressures.

**FIG. 22.2.** Optical micrograph of a conduit fabricated by extrusion from PLGA and salt crystals, a salt weight fraction of 90%, and an extrusion temperature of 250°C. Reprinted from Widmer *et al.* (1998). Copyright 1998, with permission of Elsevier Science.

## VIII. FREEZE-DRYING

Another method for rapid fabrication of scaffolds with controllable porosity and average pore diameter employs emulsion and freeze-drying. An organic solution containing dissolved polymer is combined with a suitable amount of water and emulsified until homogeneity is achieved (Whang *et al.*, 1995). The resulting emulsion is poured into a metal mold of specified dimensions and frozen with liquid nitrogen. Freeze-drying removes the water and solvent to yield scaffolds of highly interconnected pores, porosities up to 90%, and median pore diameters from 15 to 35  $\mu\text{m}$ . This technique has been utilized with many biocompatible polymers, including PGA, PLLA, PLGA, and poly(propylene fumarate) (PPF) blends. Inclusion of polymers like PPF in composite scaffolds is beneficial for adjustment of compressive strength and properties related to hydrophobicity (e.g., water penetration, scaffold degradation rates, and drug diffusion) (Hsu *et al.*, 1997). PLGA/PPF foam scaffolds exhibit a closed-pore morphology, however, an unattractive quality for most tissue-engineering applications. PLGA and PLGA-blend polymer scaffolds of greater than 1-cm thickness can be manufactured by emulsion and freeze-drying.

Non-emulsion-based freeze-drying is also capable of producing porous polymer scaffolds. Synthetic polymers dissolved in glacial organic solvents are frozen, and then the solvent is removed by freeze-drying (Hsu *et al.*, 1997). Similar techniques were utilized to create collagen scaffolds by dispersing the protein in water and freeze-drying the suspension (Yannas *et al.*, 1980). Sublimed ice crystals generate pores, with pore size being controlled by solution parameters such as freezing rate, temperature, ionic concentrations, and pH.

## IX. PHASE SEPARATION

The potential to deliver drugs and other bioactive molecules from a degradable tissue-engineering scaffold is advantageous for modulating cell differentiation and guiding tissue regeneration. Such scaffolds can be produced by a phase separation technique that does not expose the bioactive molecules to harsh organic chemicals or temperatures (Lo *et al.*, 1995). Briefly, a biocompatible polymer such as PLGA or a poly(phosphoester) is dissolved in an appropriate solvent (e.g., phenol at 55°C, dioxane at 63°C, or naphthalene at 85°C). While stirring, the bioactive molecules are added and dispersed into a homogeneous mixture and cooled below the solvent melting point until the liquid phases separate (Hua *et al.*, 2002). The polymer and solvent are quenched with liquid nitrogen, resulting in a two-phase solid. The solvent is removed by sublimation, which yields a porous scaffold with bioactive molecules embedded inside the polymer. Porosity and architecture are affected by the cooling rate and the melting temperature of the solvent relative to the polymer. Tailoring specific drug-release rates and incorporating large proteins are the major obstacles with phase separation methods of polymer scaffold fabrication.

## X. HIGH-INTERNAL-PHASE EMULSION

Porous scaffolds are typically prepared by bulk polymerization or condensation with the use of porogenic materials. An alternative method of fabrication is the polymerization of the continuous phase around aqueous droplets in an emulsion (Busby *et al.*, 2001). The setup involves a water-in-oil emulsion system with an organic phase containing the specified monomers. When the internal (droplet) phase volume fraction exceeds 74%, the emulsion is defined as a high-internal-phase emulsion (HIPE) (Lissant, 1974). Under desired HIPE conditions, polymers are synthesized and/or cross-linked to yield a solid network with interconnected pores. Polymers derived from HIPEs are dubbed PolyHIPEs. PolyHIPE foams resemble the structure of emulsion-formed scaffolds at the gel point. The morphology of the structure depends primarily on the volume fraction and the droplet radius, which can be controlled by the physical conditions of the emulsion. Total porosity is based on phase volume fraction, and scaffolds of more than 90% porosity have been produced from PolyHIPE systems. Porogens can also be incorporated into PolyHIPEs for additional porosity. Early research with PolyHIPE scaffolds used nondegradable polymers like poly(styrene), but recent work has utilized biodegradable polymers such as PLLA and PCL (Busby *et al.*, 2002). Images of PLA-MMA PolyHIPEs are shown in Fig. 22.3.

## XI. GAS FOAMING

A major concern with typical solvent-casting and particulate-leaching strategies is the use of organic solvents, remnants of which might lead to an inflammatory response after implantation. A method that avoids any organic sol-

**FIG. 22.3.** Scanning electron micrographs of PLA-MMA PolyHIPEs: (A) 0.2-M at low magnification; (B) 0.2-M at high magnification; (C) 0.4-M at low magnification; (D) 0.4-M at high magnification. Reprinted from Busby *et al.* (2002). Copyright 2002, with permission of John Wiley & Sons, Ltd.

vents is gas-foaming scaffold fabrication (Mooney *et al.*, 1996b). Compressed polymer disks (e.g., PLGA) are treated with high-pressure CO<sub>2</sub>. As the pressure is decreased, nucleation and pore formation occur in the polymer matrix based on the amount and reduction rate of pressure. The average pore size ranges from 100 to 500  $\mu\text{m}$ ; however, a drawback of this method remains its closed-pore morphology. Incorporation of a particle-leaching technique has been shown to create an open-pore network in scaffolds produced by gas foaming (Harris *et al.*, 1998). Smooth muscle cells have exhibited enhanced adhesion and proliferation to scaffolds fabricated in this manner.

## XII. POLYMER/CERAMIC COMPOSITE FABRICATION

Tissue-engineering strategies for bone replacement are unique, in that they must account for the irregular shape of most bone defects and the required mechanical strength of the scaffold. While scaffolds of polymers such as the poly( $\alpha$ -hydroxyester) family provide sufficient support in orthopedic applications, increasing the scaffold porosity drastically reduces the compressive strength (Thomson *et al.*, 1995). PLGA scaffolds containing hydroxyapatite (HA, the mineral

component of bone) fibers have been assembled using melt-molding and solvent-casting techniques (Thomson *et al.*, 1998). The greatest effects of HA on the scaffold's mechanical properties are observed when the fibers are fully dispersed throughout the polymer to maximize polymer-HA contact.

More recent methods incorporate microparticles of HA, rather than fibers, into the scaffold network. One technique uses an emulsion of PLGA and HA dissolved in chloroform with an aqueous PVA solution (Devin *et al.*, 1996). After the mixture is emulsified, it is cast into molds and vacuum dried to yield a porous PLGA/HA composite foam. The compressive strength of the scaffold was found to be proportional to its HA content. Such scaffolds exhibited compressive strengths on the same order of magnitude as cancellous bone (10–1000 MPa) (Hollister, 2005). Another method that integrates HA powder into PLGA scaffolds employs phase separation (R. Zhang and Ma, 1999). HA is dispersed in a PLGA/dioxane solution; then the blend is injected into molds and frozen. Following phase separation, the material is freeze-dried to remove the solvent. The resulting composite scaffolds contain an interconnected-pore network, with pore sizes from 30 to 100  $\mu\text{m}$  and porosity up to 95%. PLGA/HA composite scaffolds produced by solvent casting or gas

**FIG. 22.4.** Scanning electron micrographs of (A,C) surfaces and (B,D) cross sections of the PLGA/HA composite scaffolds fabricated by (A,B) the solvent-casting/particulate-leaching method and (C,D) the gas-foaming/particulate-leaching method. foaming, followed by particulate leaching, are pictured in Fig. 22.4.

### XIII. RAPID PROTOTYPING OF SOLID FREE FORMS

Another technique for the creation of scaffolds with specific three-dimensional structures is the *rapid prototyping* of solid free-form structures, which includes three-dimensional printing, laser sintering, and stereolithography. These methods require a computer model of the desired scaffold architecture from computer-assisted design (CAD) or computed tomography (CT). Although there are several approaches to this family of scaffold production, the result is a three-dimensionally accurate structure with a fully interconnected network of pores (Lam *et al.*, 2002). These methods have an advantage over conventional fabrication techniques due to their ability to create geometries with complex architectures on the micron scale.

Three-dimensional printing utilizes a simple inkjet printing system directed by the CAD program. Briefly, a thin layer of polymer powder, such as PLGA, is spread over a piston surface. The inkjet dispenses a binding liquid, which is a solvent for the polymer, in the desired pattern of the scaffold layer. After a short bonding time, the piston is lowered by the thickness of a single layer and the subsequent layers of powder and binding liquid are applied. Unbound polymer remains in the network during the fabrication process to support disconnected sections in the layer. PLLA and PLGA scaffolds produced in this manner have properties similar to those made via compression molding

(Giordano *et al.*, 1996) and show great promise in cell transplantation and vascular penetration into the implanted structure (Kim *et al.*, 1998).

Fused-deposition modeling (FDM) combines the elements of extrusion and melt molding with free-form scaffold fabrication (Leong *et al.*, 2003). Polymer stock is heated and extruded through a computer-controlled nozzle. With each layer deposited and cooled, the nozzle changes the direction of deposition to yield a porous, honeycomb-type structure. Scaffolds produced via FDM have controlled pore size, porosity, and total pore interconnectivity. FDM is used with many synthetic polymers, including PCL, PLGA, and high-density polyethylene. An FDM-fabricated scaffold with three-dimensional pore interconnectivity is shown in Fig. 22.5.

Laser sintering is similar to three-dimensional printing, but it uses a high-powered laser to sinter the polymer instead of dispensing a binding liquid. The laser selectively scans the powder polymer surface, directed by the CAD or CT computer program (K. H. Tan *et al.*, 2003). The laser beam heats the polymer above its melt temperature and fuses particles into a solid structure. Additional layers of polymer are added to the top surface and sintered accordingly. This technique has been used with biocompatible materials such as PLLA, PCL, PVA, and hydroxyapatite (K. H. Tan *et al.*, 2005). Such scaffolds were shown to be biocompatible, highly porous, and accurate to design specifications.

A popular method of fabrication by rapid prototyping is stereolithography. Stereolithography uses light to polymerize, cross-link, or harden a photosensitive material (Dhariwala *et al.*, 2004). Typically for tissue-engineering

applications, a fine layer of a solution of biocompatible polymer, photo-cross-linking initiating agent, porogen, and an appropriate solvent is placed beneath the laser. Like previous methods, the CAD software guides the laser in the desired pattern for the designed scaffold. The laser's ultraviolet light reacts with the photo-initiator to form chemical bonds between polymer chains in the specified locations. Subsequent layers of polymer solution are added and photo-cross-linked. The final product is washed to remove unreacted polymer and yield a three-dimensional structure with specific microarchitectures.

#### XIV. PEPTIDE SELF-ASSEMBLY

Since the mid-1990s, new research has studied the use of peptide nanofibers as a synthetic ECM in a tissue-engineering scaffold (S. Zhang *et al.*, 2006). While other bio-

logically derived materials, such as collagen, gelatin, and fibrin, can interact favorably with cells as compared to synthetic polymers, designer peptide fibers can self-assemble to form stable, highly ordered scaffolds on the nanoscale (Yokoi *et al.*, 2005). Self-assembling peptides typically consist of ionic, self-complementary sequences with alternating hydrophobic and hydrophilic domains (S. Zhang *et al.*, 1995). They can also include motifs favorable to cell attachment, such as the popular arginine-glycine-aspartate (RGD) peptide.

Peptide-based scaffolds have shown promise in the *in vitro* culture of osteoblasts, chondrocytes, and hepatocytes. Self-assembling peptide structures form on the nanoscale, allowing attached cells to remain in their native three-dimensional shape and not flattened like cells attached to some microscale surfaces. While the individual fibers can be as small as 5 nm, the aggregate scaffolds can reach sizes in the centimeters (Hartgerink *et al.*, 2002). A scanning electron micrograph of self-assembling peptide nanofibers is seen in Fig. 22.6. By controlling the spacing of charged and hydrophobic residues in the amino acid sequence, the geometries of the forming scaffold can be manipulated. Noncovalent bonds and ionic interactions within and between peptide molecules create functional and dynamic structures in these synthetic biological systems. Adjacent fibers can be permanently cross-linked with disulfide bonds by the strategic placement of cysteine residues. Self-assembling peptides typically form stable  $\beta$ -sheets in water or physiological solutions. Peptide amphiphiles have also been shown to form more complex architectures, such as sheets, rods, spheres, and discs. Scaffold assembly and size can be controlled by pH, peptide concentration, and divalent ion induction.

#### XV. IN SITU POLYMERIZATION

The previous scaffold fabrication techniques discuss the production of prefabricated scaffolds for surgical implantation within a defect. Although these scaffolds are

**FIG. 22.7.** Scanning electron micrograph of the cross section of a PCLF scaffold thermally cross-linked with 75 vol% salt content. Reprinted from Jabbari *et al.* (2005). Copyright 2005, with permission of the American Chemical Society.

useful in most tissue-engineering applications, many orthopedic procedures require immediate treatment in defects of irregular or unpredictable shape. In such situations, an injectable, *in situ* polymerizing or hardening polymer is advantageous. Early bone cements composed of PMMA were injected into the bone fracture space (Yaszemski *et al.*, 1996). A degradable alternative for cementing bone defects is PPF, which can be thermally cross-linked with the addition of N-vinyl pyrrolidone. Unlike PMMA, injected PPF may not result in necrosis of local tissues from the elevated temperatures of polymerization or any residual toxic monomer. Incorporation of mineral into the polymer mixture can provide added mechanical properties to the scaffold. PPF with  $\beta$ -tricalcium phosphate has shown strength similar to that of human trabecular bone (Peter *et al.*, 1997). More self-cross-linkable macromers, such as poly( $\epsilon$ -caprolactone-fumarate) (PCLF), have been developed to harden *in situ* without the aid of low-molecular-weight cross-linking agents, but with the addition of an initiator and accelerator, to form porous, biodegradable scaffolds (Jabbari *et al.*, 2005). A cross section of a thermally cross-linked PCLF scaffold is presented in Fig. 22.7.

For cartilage and most soft tissues, less compressive strength is required during tissue repair. Water-based polymer gels, or *hydrogels*, are often favorable for promoting cell migration, angiogenesis, high water content, and rapid nutrient diffusion (Bryant and Anseth, 2001). Most

hydrogels are formed by the aqueous cross-linking of poly(ethylene glycol) (PEG)-based synthetic polymers or biologically derived molecules such as gelatin and fibrin. Prior to injection, cells cultured *in vitro* can be loaded into the polymer solution and encapsulated within the cross-linked hydrogel to accelerate tissue regeneration. Like PPF, modified PEG and oligo(poly(ethylene glycol) fumarate) (OPF) can be *in situ* cross-linked with inclusion of a thermal initiator (Temenoff *et al.*, 2004).

There are a variety of strategies to create porosity within *in situ* cross-linked scaffolds. Salts or other small biocompatible molecules included in the polymer solution are able to leach out *in vivo* to create a pore network over time (Peter *et al.*, 1997). Gelatin microparticles incorporated into hydrogels are enzymatically degraded to leave pores for tissue penetration (Kasper *et al.*, 2005). Hydrogels can utilize gas bubbling to form pores during cross-linking (Behravesch *et al.*, 2002). Carbon dioxide produced from the reaction of L-ascorbic acid with sodium bicarbonate, both mixed into the polymer solution prior to injection, has been used in the synthesis of poly(propylene fumarate-co-ethylene glycol) hydrogels with greater than 80% porosity.

## XVI. CONCLUSIONS

To meet the diverse needs of tissue reconstruction and replacement, tissue-engineering strategies attempt to provide artificial, yet permanent, biological solutions. As a key component of any tissue-engineering application, scaffolds require a high porosity, adequate pore size for cell migration and nutrient diffusion, biocompatibility, biodegradability, and mechanical integrity. The selected scaffold processing technique can have a profound effect on the final properties and geometry of the scaffold. The fabrication schemes in this chapter offer a practical and promising solution for scaffolds to repair and regenerate different tissues. Each method presents distinctive advantages (e.g., the ease of processing, the ability to incorporate bioactive molecules, or increased structural properties) and limitations (e.g., applicable polymers, cost of materials or equipment). Thus there is no universal scaffold fabrication technique for all tissue-engineering applications (see Table 22.1). Depending on the tissue type and extent of regeneration, scaffold properties must be prioritized in order to select the most appropriate manufacturing method. At present, tissue engineers are working to incorporate bioactive molecules into the scaffolds, develop new scaffold materials, produce constructs with mechanical properties that match those of the specific tissue, and improve the time and costs of scaffold production.

## XVII. ACKNOWLEDGMENTS

We acknowledge financial support by the National Institutes of Health for development of tissue-engineering scaffolds (R01-AR42639, R01-AR48756, and R01-DE15164).

**Table 22.1.** Summary of scaffold fabrication techniques

<i>Technique</i>	<i>Description</i>	<i>Advantages</i>	<i>Disadvantages</i>
Fiber bonding	Individual polymer fibers bonded at intersection points	Simple procedure; high porosity and surface-area-to-volume ratio	Poor mechanical properties; limited polymer types
Electrospinning	Fibers are electrostatically spun into a nonwoven scaffold	Control over pore sizes, porosity, and fiber thickness	Pore size decreases with fiber thickness; limited mechanical properties
Solvent casting/ particulate leaching	Polymer scaffold containing porogen is solidified; then the porogen is leached out	Control over porosity, pore sizes, and crystallinity; high porosity	Limited mechanical properties; residual solvents and porogen material
Melt molding	Polymer and porogen are heated, homogenized, and cooled in a mold	Control over macrogeometry, porosity, and pore size	Temperatures unsuitable for biomolecules
Membrane lamination	Thin layers of porous scaffolds are surface bonded to yield complex architectures	Control over macrogeometry, porosity, and pore size	Limited mechanical properties; inadequate pore interconnectivity; residual solvents
Extrusion	Prefabricated membranes are extruded through nozzle; then the porogen is leached out	Control over porosity and pore size; unique macrogeometry (e.g., tubular shapes)	Limited mechanical properties; temperatures unsuitable for biomolecules
Freeze-drying	Dissolved polymer and water are emulsified and freeze-dried to remove water and solvent	Good porosity and pore interconnectivity	Limited pore sizes
Phase separation	Polymer is dissolved in melted organic solvent and then solidified with liquid nitrogen	High porosity; ability to incorporate biomolecules	Limited pore sizes; residual solvents; no control over microgeometry

High-internal-phase emulsion	Polymers are synthesized and/or cross-linked as the organic phase of a HIPE	Control over porosity, pore size, and interconnectivity	Limited mechanical properties; limited polymer types
Gas foaming	Compressed polymer is treated with high-pressure gas, leading to pore formation on depressurization	Free of harsh organic solvents; control over porosity; ability to incorporate biomolecules	Limited mechanical properties; inadequate pore interconnectivity
Polymer/ceramic composite fabrication	Scaffolds of polymers and inorganic molecules or fibers are formed by solvent-casting or melt-molding techniques	Control over porosity and pore size; enhanced mechanical properties	Residual solvents
Rapid prototyping	CAD-controlled fabrication using solvent dispensing, fused deposition, laser sintering, or stereolithography	Excellent control over geometry (macro and micro) and porosity	Limited polymer types; high equipment cost
Peptide self-assembly	Designer peptide sequences are self-assembled into spheres, fibers, or complex scaffolds	Control over porosity, pore size, and fiber diameter; bioactive degradation products	Expensive materials; complex design parameters; limited macrosizes and mechanical properties
<i>In situ</i> polymerization	Polymers are polymerized or cross-linked; scaffolds are formed postimplantation	Injectable; control over mechanical properties; ability to incorporate biomolecules	Limited porosity; residual monomers and cross-linking agents

### I. INTRODUCTION

The design and development of tissue-engineered products has benefited from many years of clinical utilization of a wide range of biodegradable polymers. Newly developed biodegradable polymers and novel modifications of previously developed biodegradable polymers have enhanced the tools available to create clinically important tissue-engineering applications. Insights gained from studies of cell-matrix interactions, cell-cell signaling, and organization of cellular components are placing increased demands on biomaterials for novel sophisticated medical implants, such as tissue engineering constructs, and continue to fuel the interest in improving the performance of existing medical-grade polymers and developing new synthetic polymers. This chapter surveys those biologically derived and synthetic biodegradable polymers that have been used or are under consideration for use in tissue-engineering applications. The polymers are described in terms of their chemical composition, breakdown products, mechanism of breakdown, mechanical properties, and clinical limitations. Also discussed are product design considerations in processing of biomaterials into a final form (e.g., gel, membrane, matrix) that will effect the desired tissue response.

### II. BIODEGRADABLE POLYMER SELECTION CRITERIA

The selection of biomaterials plays a key role in the design and development of tissue-engineering product development. While the classical selection criterion for a safe, stable implant dictated choosing a passive, inert material, it is now understood that any such device will elicit a cellular response (Peppas and Langer, 1994; Langer and Tirrell, 2004). Therefore, it is now widely accepted that a biomaterial must interact with tissue to repair, rather than act simply as a static replacement. Furthermore, biomaterials used directly in tissue repair or replacement applications (e.g., artificial skin) must be more than biocompatible; they must elicit a desirable cellular response. Consequently, a major focus of biomaterials for tissue-engineering applications centers around harnessing control over cellular interactions with biomaterials, often including components to manipulate cellular response within the supporting biomaterial as a key design component. Specific examples include protein growth factors, anti-inflammatory drugs, gene delivery vectors, and other bioactive factors to elicit the desired cellular response (see recent reviews by Murphy and Mooney, 1999, and Davies, 2004).

It is important for the tissue-engineering product developer to have several biomaterials options available, for each application calls for a unique environment for cell–cell interactions. Such applications include (1) support for new tissue growth (wherein cell–cell communication and cell availability to nutrients, growth factors, and pharmaceutically active agents must be maximized); (2) prevention of cellular activity (where tissue growth, such as in surgically induced adhesions, is undesirable); (3) guided tissue response (enhancing a particular cellular response while inhibiting others); (4) enhancement of cell attachment and subsequent cellular activation (e.g., fibroblast attachment, proliferation, and production of extracellular matrix for dermis repair); (5) inhibition of cellular attachment and/or activation (e.g., platelet attachment to a vascular graft); and (6) prevention of a biological response (e.g., blocking antibodies against homograft or xenograft cells used in organ replacement therapies).

Biodegradable polymers are applicable to those tissue-engineering products in which tissue repair or remodeling is the goal, but not where long-term materials stability is required. Biodegradable polymers must also possess (1) manufacturing feasibility, including sufficient commercial quantities of the bulk polymer; (2) the capability to form the polymer into the final product design; (3) mechanical properties that adequately address short-term function and do not interfere with long-term function; (4) low or negligible toxicity of degradation products, in terms of both local tissue response and systemic response; and (5) drug delivery compatibility in applications that call for release or attachment of active compounds.

### III. BIOLOGICALLY DERIVED BIORESORBABLES

#### Type I Collagen

Collagen is the major component of mammalian connective tissue, animal protein, accounting for approximately 30% of all protein in the human body. It is found in every major tissue that requires strength and flexibility (e.g., skin, bone). Fourteen types of collagens have been identified, the most abundant being type I (van der Rest *et al.*, 1990). Because of its abundance (it makes up more than 90% of all fibrous proteins) and its unique physical and biological properties, type I collagen has been used extensively in the formulation of biomedical materials (Pachence *et al.*, 1987; Pachence, 1996). Type I collagen is found in high concentrations in tendon, skin, bone, and fascia, which are consequently convenient and abundant sources for isolation of this natural polymer.

The structure, function, and synthesis of type I collagen has been thoroughly investigated (Piez, 1984; Tanzer and Kimura, 1988). Collagen proteins, by definition, are characterized by a unique triple helix formation extending over a

large portion of the molecule. The three peptide subunits that make up the triple helix of collagen have similar amino acid composition, each chain comprising approximately 1050 amino acid residues. The length of each subunit is ~300 nm, and the diameter of the triple helix is ~1.5 nm. The primary structure of collagen (with its high content of proline and hydroxyproline and with every third amino acid being glycine) shows a strong sequence homology across genus and adjacent family line. Because of its phylogenetically well-conserved primary sequence and its helical structure, collagen is only mildly immunoreactive (De Lusto *et al.*, 1987; Anselme *et al.*, 1990).

The individual collagen molecules will spontaneously polymerize *in vitro* into strong fibers that can be subsequently formed into larger organized structures (Piez, 1984). The collagen may be further modified to form intra- and intermolecular cross-links, which aid in the formation of collagen fibers, fibrils, and then macroscopic bundles that are used to form tissue (Nimni and Harkness, 1988). For example, tendon and ligaments comprise mainly oriented type I collagen fibrils, which are extensively cross-linked in the extracellular space. Added strength via *in vivo* cross-linking is imparted to the collagen fibers by several enzymatic (such as lysyl oxidase) and nonenzymatic reactions. The most extensive cross-linking occurs at the telopeptide portion of the molecule.

Collagen cross-linking can be enhanced after isolation through a number of well-described physical or chemical techniques (Pachence *et al.*, 1987). Increasing the intermolecular cross-links (1) increases biodegradation time, by making collagen less susceptible to enzymatic degradation; (2) decreases the capacity of collagen to absorb water; (3) decreases its solubility; and (4) increases the tensile strength of collagen fibers. The free  $\epsilon$ -amines on lysine residues on collagen can be utilized for cross-linking or can similarly be modified to link or sequester active agents. These simple chemical modifications provide a variety of processing possibilities and, consequently, the potential for a wide range of tissue-engineering applications using type I collagen.

It has long been recognized that substrate attachment sites are necessary for growth, differentiation, replication, and metabolic activity of most cell types in culture. Collagen and its integrin-binding domains (e.g., RGD sequences) assist in the maintenance of such attachment-dependent cell types in culture. For example, fibroblasts grown on collagen matrices appear to differentiate in ways that mimic *in vivo* cellular activity and to exhibit nearly identical morphology and metabolism (Silver and Pins, 1992). Chondrocytes can also retain their phenotype and cellular activity when cultured on collagen (Toolan *et al.*, 1996). Such results suggest that type I collagen can serve as tissue regeneration scaffold for any number of cellular constructs.

The recognition that collagen matrices could support new tissue growth was exploited to develop the original formulations of artificial extracellular matrices for dermal

replacements (Yannas and Burke, 1980; Yannas *et al.*, 1980; Burke *et al.*, 1981). Yannas and Burke were the first to show that the rational design and construction of an artificial dermis could lead to the synthesis of a dermislike structure whose physical properties “would resemble dermis more than they resembled scar” (Burke *et al.*, 1981). They created a collagen–chondroitin sulfate composite matrix with a well-described pore structure and cross-linking density that optimizes regrowth while minimizing scar formation (Dagalakis *et al.*, 1980). The reported clinical evidence and its simplicity of concept make this device an important potential tool for the treatment of severely burned patients (Heimbach *et al.*, 1988).

Collagen gels were used by Eugene Bell at the Massachusetts Institute of Technology to create a cell-based system for dermal replacement (Bell *et al.*, 1991; Parenteau, 1999). This living-skin equivalent (commercially known as Alpligraf™) is composed of a mixture of live human fibroblasts and soluble collagen in the form of a contracted gel, which is then seeded with keratinocytes. A number of clinical investigators have tested such cell-based collagen dressings for use as a skin graft substitute for chronic wounds and burn patients.

The advantageous properties of collagen for supporting tissue growth have been used in conjunction with the superior mechanical properties of synthetic biodegradable polymer systems to make hybrid tissue scaffolds for bone and cartilage (Hsu *et al.*, 2006; Chen *et al.*, 2006, 2004; Sato *et al.*, 2004). These hybrid systems show superior cell adhesion, interaction, and proliferation as compared to the synthetic polymer system alone. Collagen has also been used to improve cell interactions with electrospun nanofibers of poly(hydroxy acids), such as poly(lactic acid), poly(glycolic acid), poly( $\epsilon$ -caprolactone), and their copolymers (Venugopal *et al.*, 2005; He *et al.*, 2005a, 2005b).

### Glycosaminoglycans

Glycosaminoglycans (GAGs), which consist of repeating disaccharide units in linear arrangement, usually include a uronic acid component (such as glucuronic acid) and a hexosamine component (such as N-acetyl-D-glucosamine). The predominant types of GAGs attached to naturally occurring core proteins of proteoglycans include chondroitin sulfate, dermatan sulfate, keratan sulfate, and heparan sulfate (Heinegard and Paulson, 1980; Naeme and Barry, 1993). The GAGs are attached to the core protein by specific carbohydrate sequences containing three or four monosaccharides.

The largest GAG, hyaluronic acid (hyaluronan), is an anionic polysaccharide with repeating disaccharide units of N-acetylglucosamine and glucuronic acid, with unbranched units ranging from 500 to several thousand. Hyaluronic acid can be isolated from natural sources (e.g., rooster combs) or via microbial fermentation (Balazs, 1983). Because of its water-binding capacity, dilute solutions of hyaluronic acid form viscous solutions.

Like collagen, hyaluronic acid can be easily chemically modified, as by esterification of the carboxyl moieties, which reduces its water solubility and increases its viscosity (Balazs, 1983; Sung *et al.* and Topp, 1994). Hyaluronic acid can be cross-linked to form molecular weight complexes in the range  $8$  to  $24 \times 10^6$  or to form an infinite molecular network (gels). In one method, hyaluronic acid is cross-linked using aldehydes and small proteins to form bonds between the C—OH groups of the polysaccharide and the amino or imino groups of the protein, thus yielding high-molecular-weight complexes (Balazs and Leshchiner, 1986). Other cross-linking techniques include the use of vinyl sulfone, which reacts to form an infinite network through sulfonyl-bis-ethyl cross-links (Balazs and Leshchiner, 1985). The resultant infinite network gels can be formed into sheaths, membranes, tubes, sleeves, and particles of various shapes and sizes. No species variations have been found in the chemical and physical structure of hyaluronic acid. The fact that it is not antigenic, eliciting no inflammatory or foreign-body reaction, make it desirable as a biomaterial. Its main drawbacks in this respect are its residence time and the limited range of its mechanical properties.

Because of its relative ease of isolation and modification and its superior ability in forming solid structures, hyaluronic acid has become the preferred GAG in medical device development. It has been used as a viscoelastic during eye surgery since 1976 and has undergone clinical testing as a means of relieving arthritic joints (Weiss and Balazs, 1987). In addition, gels and films made from hyaluronic acid have shown clinical utility to prevent postsurgical adhesion formation (Urmann *et al.*, 1991; Holzman *et al.*, 1994; Medina *et al.*, 1995).

The benzyl ester of hyaluronic acid, sold under the trade name HYAFF-11, has been studied for use in vascular grafts (Lepidi *et al.*, 2006; Turner *et al.*, 2004), to support chondrocyte growth (Grigolo *et al.*, 2002; Solchaga *et al.*, 2000) and for bone tissue engineering (Giordano *et al.*, 2006; Sanginario *et al.*, 2006).

### Chitosan

Chitosan is a biosynthetic polysaccharide that is the deacylated derivative of chitin. Chitin is a naturally occurring polysaccharide that can be extracted from crustacean exoskeletons or generated via fungal fermentation processes. Chitosan is a  $\beta$ -1,4-linked polymer of 2-amino-2-deoxy-D-glucose; it thus carries a positive charge from amine groups (Kaplan *et al.*, 1994). It is hypothesized that the major path for chitin and chitosan breakdown *in vivo* is through lysozyme, which acts slowly to depolymerize the polysaccharide (Taravel and Domard, 1993). The biodegradation rate of the polymer is determined by the amount of residual acetyl content, a parameter that can easily be varied. Chemical modification of chitosan produces materials with a variety of physical and mechanical properties (Muzzarelli *et al.*, 1988; Wang *et al.*, 1988; Laleg and Pikulik,

1991). For example, chitosan films and fibers can be formed utilizing cross-linking chemistries, adapted techniques for altering from other polysaccharides, such as treatment of amylose with epichlorohydrin (Wei *et al.*, 1977). Like hyaluronic acid, chitosan is not antigenic and is a well-tolerated implanted material (Malette *et al.*, 1986).

Chitosan has been formed into membranes and matrices suitable for several tissue-engineering applications (Hirano, 1989; Sandford, 1989; Byrom, 1991; Madhally and Matthew, 1999; Shalaby *et al.*, 2004) as well as conduits for guided nerve regeneration (Huang *et al.*, 2005; Bini *et al.*, 2005). Chitosan matrix manipulation can be accomplished using the inherent electrostatic properties of the molecule. At low ionic strength, the chitosan chains are extended via the electrostatic interaction between amine groups, whereupon orientation occurs. As ionic strength is increased, and chain-chain spacing diminished, the consequent increase in the junction zone and stiffness of the matrix result in increased average pore size. Chitosan gels, powders, films, and fibers have been formed and tested for such applications as encapsulation, membrane barriers, contact lens materials, cell culture, and inhibitors of blood coagulations (East *et al.*, 1989).

### Polyhydroxyalkanoates

Polyhydroxyalkanoate (PHA) polyesters are degradable, biocompatible, thermoplastic materials made by several microorganisms (Miller and Williams, 1987; Gogolewski *et al.*, 1993). They are intracellular storage polymers whose function is to provide a reserve of carbon and energy (Dawes and Senior, 1973). Depending on growth conditions, bacterial strain, and carbon source, the molecular weights of these polyesters can range from tens into the hundreds of thousands. Although the structures of PHA can contain a variety of *n*-alkyl side-chain substituents (see Structure 23.1), the most extensively studied PHA is the simplest: poly(3-hydroxybutyrate) (PHB).

ICI developed a biosynthetic process for the manufacture of PHB, based on the fermentation of sugars by the bacterium *Alcaligenes eutrophus*. PHB homopolymer, like

**STRUCTURE 23.1.** Poly(*b*-hydroxybutyrate) and copolymers with hydroxyvaleric acid. For a homopolymer of HB, Y = 0; commonly used copolymer ratios are 7, 11, or 22 mole percent of hydroxyvaleric acid.

all other PHA homopolymers, is highly crystalline, extremely brittle, and relatively hydrophobic. Consequently, the PHA homopolymers have degradation times *in vivo* on the order of years (Holland *et al.*, 1987; Miller and Williams, 1987). The copolymers of PHB with hydroxyvaleric acid are less crystalline, more flexible, and more readily processible, but they suffer from the same disadvantage of being too hydrolytically stable to be useful in short-term applications when resorption of the degradable polymer within less than one year is desirable.

PHB and its copolymers with up to 30% of 3-hydroxyvaleric acid are now commercially available under the trade name Biopol. It was found previously that a PHA copolymer of 3-hydroxybutyrate and 3-hydroxyvalerate, with a 3-hydroxyvalerate content of about 11%, may have an optimum balance of strength and toughness for a wide range of possible applications. PHB has been found to have low toxicity, in part due to the fact that it degrades *in vivo* to D-3-hydroxybutyric acid, a normal constituent of human blood. Applications of these polymers previously tested or now under development include controlled drug release, artificial skin, and heart valves as well as such industrial applications as paramedical disposables (Yasin *et al.*, 1989; Doi *et al.*, 1990; Sodian *et al.*, 2000). Sutures are the main usage for polyhydroxyalkanoates, although a number of clinical applications and trials are ongoing (Ueda and Tabata, 2003).

### Experimental Biologically Derived Bioresorbables

Synthetic biomolecules are beginning to find a place in the repertoire of biomaterials for medical applications. Model synthetic proteins structurally similar to elastin have been formulated by Urry and coworkers (Nicol *et al.*, 1992; Urry, 1995). Using a combination of solid-phase peptide chemistry and genetically engineered bacteria, they synthesized several polymers having homologies to the elastin repeat sequences of valine-proline-glycine-valine-glycine repeat (VPGVG). The constructed amino acid polymers were formed into films and then cross-linked. The resultant films have intriguing mechanical responses, such as a reverse phase transition. When a film is heated, its internal order increases, translating into substantial contraction with increasing temperature (Urry, 1995). The films can be mechanically cycled many times, and the phase transition of the polymers can be varied by amino acid substitution. Copolymers of VPGVG and VPGXG have been constructed (where X is the substitution) that show a wide range of transition temperatures (Urry, 1995). Several medical applications are under consideration for this system, including musculoskeletal repair mechanisms, ophthalmic devices, and mechanical and/or electrically stimulated drug delivery.

Other investigators, notably Tirrell and Cappello, have combined techniques from molecular and fermentation biology to create novel protein-based biomaterials

(Cappello, 1992; J. P. Anderson *et al.*, 1994; Tirrell *et al.*, 1994; van Hest and Tirrell, 2001). These protein polymers are based on repeat oligomeric peptide units, which can be controlled via the genetic information inserted into the producing bacteria. It has been shown that the mechanical properties and the biological activities of these protein polymers can be programmed, suggesting a large number of potential biomedical applications (Krejchi *et al.*, 1994).

Another approach to elicit an appropriate cellular response to a biomaterial is to graft active peptides to the surface of a biodegradable polymer. For example, peptides containing the RGD sequence have been grafted to various biodegradable polymers to provide active cell-binding surfaces (Hubbell, 1995). Similarly, Panitch *et al.* (1999) incorporated oligopeptides containing the REDV sequence to stimulate endothelial cell binding for vascular grafts.

#### IV. SYNTHETIC POLYMERS

From the beginnings of the material sciences, the development of highly stable materials has been a major research challenge. Today, many polymers are available that are virtually indestructible in biological systems, e.g., Teflon, Kevlar, and poly(ether-ether-ketone). On the other hand, the development of degradable biomaterials is a relatively new area of research. The variety of available degradable biomaterials is still too limited to cover a wide enough range of diverse material properties. Thus, the design and synthesis of new degradable biomaterials is currently an important research challenge.

Due to the efforts of a wide range of research groups, a large number of different polymeric compositions and structures have been suggested as degradable biomaterials. However, in most cases no attempts have been made to develop these new materials for specific medical applications. Thus, detailed toxicological studies *in vivo*, investigations of degradation rate and mechanism, and careful evaluations of the physicomaterial properties have so far been published for only a very small fraction of those polymers. This leaves the tissue engineer with only a relatively limited number of promising polymeric compositions to choose from. The following section is limited to a review of the most commonly investigated classes of biodegradable synthetic polymers.

##### Poly( $\alpha$ -hydroxy acids)

Naturally occurring hydroxy acids, such as glycolic, lactic, and  $\epsilon$ -caproic acids, have been utilized to synthesize an array of useful biodegradable polymers for a variety of medical product applications. As an example, bioresorbable surgical sutures made from poly( $\alpha$ -hydroxy acids) have been in clinical use since 1970; other implantable devices made from these versatile polymers (e.g., internal fixation devices for orthopedic repair) are becoming part of standard surgical protocol (Helmus and Hubbell, 1993; Shalaby and Johnson, 1994; Hubbell, 1995).

The ester bond of the poly(hydroxy acids) are cleaved by hydrolysis, which results in a decrease in the polymer molecular weight (but not mass) of the implant (Vert and Li, 1992). This initial degradation occurs until the molecular weight is less than 5000 Da, at which point cellular degradation takes over. The final degradation and resorption of the poly(hydroxy acid) implants involves inflammatory cells (such as macrophages, lymphocytes, and neutrophils). Although this late-stage inflammatory response can have a deleterious effect on some healing events, these polymers have been successfully employed as matrices for cell transplantation and tissue regeneration (Freed *et al.*, 1994a, 1994b). The degradation rate of these polymers is determined by initial molecular weight, exposed surface area, crystallinity, and (in the case of copolymers) the ratio of the hydroxy acid monomers.

The poly(hydroxy acid) polymers have a modest range of mechanical properties and a correspondingly modest range of processing conditions. Nevertheless, these thermoplastics can generally be formed into films, tubes, and matrices using such standard processing techniques as molding, extrusion, solvent casting, and spin casting. Ordered fibers, meshes, and open-cell foams have been formed to fulfill the surface area and cellular requirements of a variety of tissue-engineering constructs (Helmus and Hubbell, 1993; Freed *et al.*, 1994; Hubbell, 1995; Wintermantel *et al.*, 1996). The poly(hydroxy acid) polymers have also been combined with other materials, e.g., poly(ethylene glycol), to modify the cellular response elicited by the implant and its degradation products (Sawhney *et al.*, 1993).

##### Poly(glycolic acid), Poly(lactic acid), and Their Copolymers

Poly(glycolic acid) (PGA), poly(lactic acid) (PLA), and their copolymers are the most widely used synthetic degradable polymers in medicine. Of this family of linear aliphatic polyesters, PGA has the simplest structure (see Structure 23.2) and consequently enjoys the largest associated literature base. Since PGA is highly crystalline, it has a high melting point and low solubility in organic solvents. PGA was used in the development of the first totally synthetic absorbable suture (Frazza and Schmitt, 1971). The crystallinity of PGA in surgical sutures is typically in the range 46–52% (Gilding and Reed, 1979). Due to its hydrophilic nature, surgical sutures made of PGA tend to lose their mechanical strength rapidly, typically over a period of two to four weeks post-implantation (Reed and Gilding, 1981).

**STRUCTURE 23.2.** Poly(glycolic acid) (PGA).

**STRUCTURE 23.3.** Poly(lactic acid) (PLA).

In order to adapt the materials properties of PGA to a wider range of possible applications, researchers undertook an intensive investigation of copolymers of PGA with the more hydrophobic poly(lactic acid) (PLA). Alternative sutures composed of copolymers of glycolic acid and lactic acid are currently marketed under the trade names Vicryl and Polyglactin 910.

Due to the presence of an extra methyl group in lactic acid, PLA (Structure 23.3) is more hydrophobic than PGA. The hydrophobicity of high-molecular-weight PLA limits the water uptake of thin films to about 2% (Gilding and Reed, 1979) and results in a rate of backbone hydrolysis lower than that of PGA (Reed and Gilding, 1981). In addition, PLA is more soluble in organic solvents than is PGA.

It is noteworthy that there is no linear relationship between the ratio of glycolic acid to lactic acid and the physicomechanical properties of their copolymers. Whereas PGA is highly crystalline, crystallinity is rapidly lost in PGA–PLA copolymers. These morphological changes lead to an increase in the rates of hydration and hydrolysis. Thus, copolymers tend to degrade more rapidly than either PGA or PLA (Gilding and Reed, 1979; Reed and Gilding, 1981).

Since lactic acid is a chiral molecule, it exists in two stereoisomeric forms that give rise to four morphologically distinct polymers. D-PLA and L-PLA are the two stereoregular polymers, D,L-PLA is the racemic polymer obtained from a mixture of D- and L-lactic acid, and meso-PLA can be obtained from D,L-lactide. The polymers derived from the optically active D and L monomers are semicrystalline materials, while the optically inactive D,L-PLA is always amorphous. Generally, L-PLA is more frequently employed than D-PLA, since the hydrolysis of L-PLA yields L(+)-lactic acid, which is the naturally occurring stereoisomer of lactic acid.

The differences in the crystallinity of D,L-PLA and L-PLA have important practical ramifications: Since D,L-PLA is an amorphous polymer, it is usually considered for applications such as drug delivery, where it is important to have a homogeneous dispersion of the active species within a monophasic matrix. On the other hand, the semicrystalline L-PLA is preferred in applications where high mechanical strength and toughness are required — for example, sutures and orthopedic devices (Christel *et al.*, 1982; Leenstagg *et al.*, 1987; Vainionpää *et al.*, 1987).

Recently, PLA, PGA, and their copolymers have been combined with bioactive ceramics such as Bioglass particles and hydroxyapatite that stimulate bone regeneration while

greatly improving the mechanical strength of the composite material (Rezwan *et al.*, 2006). Bioglass particles combined with D,L-PLA-co-PGA have also been shown to be angiogenic, suggesting a novel approach for providing a vascular supply to implanted devices (Day *et al.*, 2005). Chu has recently reviewed the most significant and successful biomedical applications of the poly(hydroxy acids) (Chu, 2003). PLA, PGA, and their copolymers are also being intensively investigated for a large number of drug delivery applications. This research effort has been comprehensively reviewed by Lewis (1990).

Some controversy surrounds the use of these materials for orthopedic applications. According to one review of short- and long-term response to resorbable pins made from either PGA or PGA:PLA copolymer in over 500 patients, 1.2% required reoperation due to device failure, 1.7% suffered from bacterial infection of the operative wound, and 7.9% developed a late noninfectious inflammatory response that warranted operative drainage (Böstman, 1991). Subsequently it has become evident that the delayed inflammatory reaction represents the most serious complication of the use of the currently available degradable fixation devices. The mean interval between fixation and the clinical manifestation of this reaction is 12 weeks for PGA and can be as long as three years for the more slowly degrading PLA (Böstman, 1991). Whether avoiding reoperation to remove a metal implant outweighs an approximately 8% risk of severe inflammatory reaction is a difficult question; in any event, an increasing number of trauma centers have suspended the use of these degradable fixation devices. It has been suggested that the release of acidic degradation products (glycolic acid for PGA, lactic acid for PLA, and glyoxylic acid for polydioxanone) contributes to the observed inflammatory reaction. Thus, the late inflammatory response appears to be a direct consequence of the chemical composition of the polymer degradation products, for which there is currently no prophylactic measure (Böstman, 1991). *In vitro* and animal experiments indicate that incorporation of alkaline salts or antibodies to inflammatory mediators may diminish the risk of a late inflammatory response (Böstman and Pihlajamäki, 2000). A more desirable solution to these problems for orthopedic (and perhaps other) applications requires the development of a polymer that is more hydrophobic than PGA or PLA, degrades somewhat more slowly, and does not release acidic degradation products on hydrolysis.

### Polydioxanone (PDS)

This poly(ether-ester) is prepared by a ring-opening polymerization of *p*-dioxanone. PDS has gained increasing interest in the medical field and pharmaceutical field due to its degradation to low toxicity monomers *in vivo*. PDS has a lower modulus than PLA or PGA; thus it became the first degradable polymer to be used to make a monofilament suture. PDS has also been introduced to the market as a

suture clip as well as more recently as a bone pin marketed under the name ORTHOSRB in the United States and Ethipin in Europe (Ray *et al.*, 1981; Greisler *et al.*, 1987; Mäkelä *et al.*, 1989).

### Poly( $\epsilon$ -caprolactone)

Poly( $\epsilon$ -caprolactone) (PCL) (Structure 23.4) is an aliphatic polyester that has been intensively investigated as a biomaterial (Pitt, 1990). The discovery that PCL can be degraded by microorganisms led to evaluation of PCL as a biodegradable packaging material (Pitt, 1990). Later, it was discovered that PCL can also be degraded by a hydrolytic mechanism under physiological conditions (Pitt *et al.*, 1981). Under certain circumstances, cross-linked PCL can be degraded enzymatically, leading to “enzymatic surface erosion” (Pitt *et al.*, 1981). Low-molecular-weight fragments of PCL are reportedly taken up by macrophages and degraded intracellularly, with a tissue reaction similar to that of other poly(hydroxy acids) (Pitt *et al.*, 1984). Compared with PGA or PLA, the degradation of PCL is significantly slower. PCL is therefore most suitable for the design of long-term, implantable systems such as Capronor, a one-year implantable contraceptive device (Pitt, 1990).

Poly( $\epsilon$ -caprolactone) exhibits several unusual properties not found among the other aliphatic polyesters. Most noteworthy are its exceptionally low glass transition temperature of  $-62^{\circ}\text{C}$  and its low melting temperature of  $57^{\circ}\text{C}$ . Another unusual property of poly( $\epsilon$ -caprolactone) is its high thermal stability. Whereas other tested aliphatic polyesters had decomposition temperatures ( $T_d$ ) between  $235$  and  $255^{\circ}\text{C}$ , poly( $\epsilon$ -caprolactone) has a  $T_d$  of  $350^{\circ}\text{C}$ , which is more typical of poly(ortho esters) than of aliphatic polyesters (Engelberg and Kohn, 1991). PCL is a semicrystalline polymer with a low glass transition temperature of about  $-60^{\circ}\text{C}$ . Thus, PCL is always in a rubbery state at room temperature. Among the more common aliphatic polyesters,

**STRUCTURE 23.4.** Poly( $\epsilon$ -caprolactone).

this is an unusual property, which undoubtedly contributes to the very high permeability of PCL for many therapeutic drugs (Pitt *et al.*, 1987).

Another interesting property of PCL is its propensity to form compatible blends with a wide range of other polymers (Koleske, 1978). In addition,  $\epsilon$ -caprolactone can be copolymerized with numerous other monomers (e.g., ethylene oxide, chloroprene, THF,  $\delta$ -valerolactone, 4-vinylanisole, styrene, methyl methacrylate, vinylacetate). Particularly noteworthy are copolymers of  $\epsilon$ -caprolactone and lactic acid that have been studied extensively (Pitt *et al.*, 1981; Feng *et al.*, 1983). PCL and copolymers with PLA have been electron-spun to create nanofibrous tissue-engineered scaffolds that show promise for vascular applications (Venugopal *et al.*, 2005; He *et al.*, 2005a, 2005b; Xu *et al.*, 2004). The toxicology of PCL has been extensively studied as part of the evaluation of Capronor. Based on a large number of tests, the monomer,  $\epsilon$ -caprolactone, and the polymer, PCL, are currently regarded as nontoxic and tissue-compatible materials. Consequently, clinical studies of the Capronor system are currently in progress (Kovalevsky and Barnhart, 2001).

It is interesting to note that in spite of its versatility, PCL has so far been predominantly considered for controlled-release drug delivery applications. In Europe, PCL is being used as a biodegradable staple, and it stands to reason that PCL (or blends and copolymers with PCL) will find additional medical applications in the future. The most recent, comprehensive review of the status of PCL has been by Pitt (1990).

### Poly(orthoesters)

Poly(ortho esters) are a family of synthetic degradable polymers that have been under development for several years (Heller *et al.*, 1990) (Structure 23.5). Devices made of poly(ortho esters) can be formulated in such a way that the device undergoes “surface erosion” — that is, the polymeric device degrades at its surface only and will thus tend to become thinner over time rather than crumbling into pieces. Since surface-eroding, slablike devices tend to release drugs embedded within the polymer at a constant rate, poly(ortho esters) appear to be particularly useful for controlled-release drug delivery (Heller, 1988); this interest is reflected by the many descriptions of these applications in the literature (Heller and Daniels, 1994).

**STRUCTURE 23.5.** Poly(orthoesters). The specific composition shown here is a terpolymer of hexadecanol (1,6-HD), *trans*-cyclohexyldimethanol (*t*-CDM), and DETOSU.

There are two major types of poly(ortho esters). Originally, poly(ortho esters) were prepared by the condensation of 2,2-diethoxytetrahydrofuran and a dialcohol (Cho and Heller, 1978) and marketed under the trade names Chronomer and Alzamer. Upon hydrolysis, these polymers release acidic by-products that autocatalyze the degradation process, resulting in degradation rates that increase with time. Later, Heller *et al.* (1980) synthesized a new type of poly(ortho ester) based on the reaction of 3,9-bis(ethylidene 2,4,8,10-tetraoxaspiro {5,5} undecane) (DETOSU) with various dialcohols. These poly(ortho esters) do not release acidic by-products upon hydrolysis and thus do not exhibit autocatalytically increasing degradation rates.

### Polyurethanes

Polyurethanes, polymers in which the repeating unit contains a urethane moiety, were first produced by Bayer in 1937 (Structure 23.6). These polymers are typically produced through the reaction of a diisocyanate with a polyol. Conventional polyols are polyethers or polyesters. The resulting polymers are segmented block copolymers, with the polyol segment providing a low-glass-transition-temperature (i.e., <25°C) soft segment and the diisocyanate component, often combined with a hydrocarbon chain extender, providing the hard segment. A wide range of physical and mechanical properties have been realized with commercial polyurethanes.

Polyurethanes have been used for nearly 50 years in biomedical applications, particularly as the blood-contacting material in cardiovascular devices. Intended as nonbiodegradable coatings, polyurethanes fell out of favor with the failure of pacemaker leads and breast implant coatings. Subsequent studies, as reviewed by Santerre *et al.* (2005), have elucidated much about the behavior of polyurethanes in biological systems. Elucidation of the biodegradation mechanism and its dependence on the polyurethane structure and composition have led to the development of biodegradable polyurethanes for a variety of tissue-engineering applications, such as myocardial repair (McDevitt *et al.*, 2003) and vascular tissues (Stankus *et al.*, 2005). Design of biodegradable polyurethanes has required alternative diisocyanate compounds. The traditional aromatic diisocyanates are putative carcinogenic compounds. Biodegradable

polymers are made from diisocyanates, such as lysine-diisocyanate or hexamethylene diisocyanate, that release nontoxic degradation products such as lysine.

The polyol or soft-segment portion of biodegradable polyurethanes is used to modify the degradation rate (Santerre *et al.*, 2005). Poly( $\alpha$ -hydroxy acids), including PLA, PGA, and PCL, have been used as soft segments for biodegradable polyurethanes (Gorna and Gogolewski, 2002; Cohn *et al.*, 2002).

An interesting application of polyurethanes was developed by Santerre *et al.* where fluoroquinolone antimicrobial drugs were incorporated into the polymer as hard-segment monomers (Woo *et al.*, 2000; Santerre *et al.*, 2005). This led to the design of drug polymers (trade name, Epidel) that release the drug when degraded by enzymes generated by an inflammatory response. This is an example of a smart system, in that antibacterial agents are released only while inflammation is present. Once healing occurs, the enzyme level drops and the release of drug diminishes.

### Poly(anhydrides)

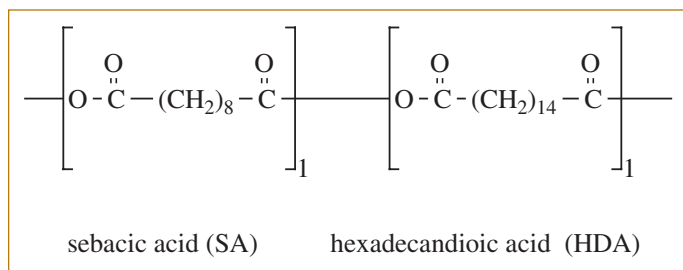

Polyanhydrides (Structure 23.7) were first investigated in detail by Hill and Carothers (1932) and were considered in the 1950s for possible applications as textile fibers (Conix, 1958). Their low hydrolytic stability, their major limitation for industrial applications, was later recognized as a potential advantage by Langer *et al.* (Rosen *et al.*, 1983), who suggested the use of polyanhydrides as degradable biomaterials. A study of the synthesis of high-molecular-weight polyanhydrides has been published by Domb *et al.* (1989, 1994).

A comprehensive evaluation of the toxicity of the polyanhydrides showed that, in general, the polyanhydrides possessed excellent *in vivo* biocompatibility (Laurencin *et al.*, 1990). The most immediate applications for polyanhydrides are in the field of drug delivery, although tissue-engineering applications are also being developed (Katti and Laurencin, 2003). Drug-loaded devices are best prepared by compression molding or microencapsulation (Mathiowitz *et al.*, 1988). A wide variety of drugs and proteins including insulin, bovine growth factors, angiogenesis inhibitors (e.g., heparin and cortisone), enzymes (e.g., alkaline phosphatase and *b*-galactosidase), and anesthetics have been incorporated into polyanhydride matrices, and

**STRUCTURE 23.6.** Polyurethane.

**STRUCTURE 23.7.** Poly(SA-HDA anhydride). This composition represents one of many polyanhydrides that were explored. The clinically relevant polyanhydrides are copolymers of sebacic acid and *p*-carboxy-phenoxypropane.

their *in vitro* and *in vivo* release characteristics have been evaluated (Chasin *et al.*, 1990). One of the most aggressively investigated uses of the polyanhydrides is for the delivery of chemotherapeutic agents. One particular example of this application is the delivery of BCNU (bis-chloroethylnitrosourea) to the brain for the treatment of glioblastoma multiformae, a universally fatal brain cancer (Langer, 1990). For this application, polyanhydrides derived from bis-*p*-(carboxyphenoxy propane) and sebacic acid received FDA regulatory clearance in the fall of 1996 and are currently being marketed under the name Gliadel®.

### Polyphosphazenes

Polyphosphazenes (Structure 23.8) consist of an inorganic phosphorous-nitrogen backbone, in contrast to the commonly employed hydrocarbon-based polymers (Scopelianos, 1994; Heyde and Schacht, 2004). Consequently, the phosphazene backbone undergoes hydrolysis to phosphate and ammonium salts, with the concomitant release of the side group. Of the numerous polyphosphazenes that have been synthesized, those that have some potential use for medical products are substituted with amines of low  $pK_a$  and those with activated alcohol moieties (Allcock, 1990; Crommen *et al.*, 1992; Laurencin *et al.*, 1993). Singh *et al.* (2006) have modified the side groups to tune polyphosphazene properties, such as glass transition temperature, degradation rate, surface wettability, tensile strength, and elastic modulus, enabling these polymers to be considered for a wider range of biomedical applications. The most extensively studied polyphosphazenes are hydrophobic, having fluoroalkoxy side groups. In part, these materials are of interest because of their expected minimal tissue interaction, which is similar to Teflon.

Aryloxyphosphazenes and closely related derivatives have also been extensively studied. One such polymer can be cross-linked with dissolved cations such as calcium to form a hydrogel matrix because of its polyelectrolytic nature (Allcock and Kwon, 1989). Using methods similar to alginate encapsulation, microspheres of aryloxyphosphazene have been used to encapsulate hybridoma cells without affecting their viability or their capacity to produce antibodies. Interaction with poly(L-lysine) produced a semipermeable

**STRUCTURE 23.8.** Polyphosphazene. Shown here is a polymer containing an amino acid ester attached to the phosphazene backbone.

membrane. Similar materials have been synthesized that show promise in blood contacting and with novel drug delivery applications.

### Poly(amino acids) and Pseudo-Poly(amino acids)

Since proteins are composed of amino acids, many researchers have tried to develop synthetic polymers derived from amino acids to serve as models for structural, biological, and immunological studies. In addition, many different types of poly(amino acids) have been investigated for use in biomedical applications (J. M. Anderson *et al.*, 1985). Poly(amino acids) are usually prepared by the ring-opening polymerization of the corresponding *N*-carboxy anhydrides that are obtained by reaction of the amino acid with phosphine (Bamford *et al.*, 1956).

Poly(amino acids) have several potential advantages as biomaterials. A large number of polymers and copolymers can be prepared from a variety of amino acids. The side chains offer sites for the attachment of small peptides, drugs, cross-linking agents, or pendent groups that can be used to modify the physicomaterial properties of the polymer. Since these polymers release naturally occurring amino acids as the primary products of polymer backbone cleavage, their degradation products may be expected to show a low level of systemic toxicity.

Poly(amino acids) have been investigated as suture materials (Spira *et al.*, 1969), as artificial skin substitutes (Aiba *et al.*, 1985), and as drug delivery systems (Mittra *et al.*, 1979; McCormick-Thomson and Duncan, 1989). Various drugs have been attached to the side chains of poly(amino acids), usually via a spacer unit that distances the drug from the backbone. Poly(amino acid)-drug combinations investigated include poly(L-lysine) with methotrexate and pepstatin (Campbell *et al.*, 1980) and poly(glutamic acid) with adriamycin and norethindrone (van Heeswijk *et al.*, 1985). Short amino acid sequences such as RGD and RGDS, strong promoters of specific cell adhesion, have been coupled to other biodegradable polymers to promote cell growth in tissue-engineering applications (Masuko *et al.*, 2005; Yang *et al.*, 2005).

Despite their apparent potential as biomaterials, poly(amino acids) have actually found few practical applications. *N*-carboxy anhydrides, the starting materials, are expensive to make and difficult to handle because of their high reactivity and moisture sensitivity. Most poly(amino acids) are highly insoluble and nonprocessable materials. Since poly(amino acids) degrade via enzymatic hydrolysis of the amide bond, it is difficult to reproduce and control their degradation *in vivo* because the level of enzymatic activity varies from person to person. Furthermore, the antigenicity of polymers containing three or more amino acids excludes their use in biomedical applications (J. M. Anderson *et al.*, 1985). Because of these difficulties, only a few poly(amino acids), usually derivatives of poly(glutamic acid) carrying various pendent chains at the  $\gamma$ -carboxylic acid group, are currently being investigated as implant materials (Lescure *et al.*, 1989).

As an alternative approach, Kohn *et al.* have replaced the peptide bonds in the backbone of synthetic poly(amino acids) by a variety of such “nonamide” linkages as ester, iminocarbonate, urethane, and carbonate bonds (James and Kohn, 1997; Kemnitzer and Kohn, 1997). The term *pseudo-poly(amino acid)* is used to denote this new family of polymers, in which naturally occurring amino acids are linked together by nonamide bonds.

The use of such backbone-modified pseudo-poly(amino acids) as biomaterials was first suggested in 1984 (Kohn and Langer, 1984). The first pseudo-poly(amino acids) investigated were a polyester from *N*-protected *trans*-4-hydroxy-L-proline and a polyiminocarbonate from tyrosine dipeptide (Kohn and Langer, 1985, 1987). Several studies indicate that the backbone modification of conventional

poly(amino acids) in general improves their physicochemical properties (Ertel and Kohn, 1994; Fiordeliso, *et al.*, 1994; James and Kohn, 1997). This approach is applicable to, among other materials, serine, hydroxyproline, threonine, tyrosine, cysteine, glutamic acid, and lysine. It is limited only by the requirement that the nonamide backbone linkages give rise to polymers with desirable material properties. Additional pseudo-poly(amino acids) can be obtained by considering dipeptides as monomeric starting materials. Hydroxyproline-derived polyesters (Kohn and Langer, 1987; Yu *et al.*, 1987; Yu-Kwon and Langer, 1989), serine-derived polyesters (Zhou and Kohn, 1990), and tyrosine-derived polyiminocarbonates (Kohn and Langer, 1987; Pulapura *et al.*, 1990) and polycarbonates (Pulapura and Kohn, 1992) represent specific embodiments of these synthetic concepts.

## V. CREATING MATERIALS FOR TISSUE-ENGINEERED PRODUCTS

As described in this chapter, the bulk polymer properties and the cellular response to biomaterials are important selection criteria for the design of a tissue-engineered product. In addition, the ability to mold the biomaterial into the appropriate cellular-level architecture must be considered, and such architecture must be compatible with the desired tissue response. Details such as pore size, pore structure (isotropic vs. anisotropic), and oriented topography, such as aligned grooves, are often critical for forming tissue with the proper cell morphology, orientation, arrangement of intercellular material, and the relationship between different cell types (Curtis and Riehle, 2001).

In recent years, the selection of appropriate biomaterials has been aided by the development of combinatorial methods and sophisticated modeling techniques that allow prediction of polymer properties and cellular response to the material (Smith *et al.*, 2005, 2004; Kholodovych *et al.*, 2004; Thorstenson and Narasimhan, 2006). Such techniques promise to greatly expand the universe of biodegradable polymers for tissue-engineering applications.

Hubbell classified approaches to choosing biomaterials for various tissue-engineering applications according to type of tissue response sought: (1) conducting tissue responses and architectures; (2) inducing tissue responses and architectures; and (3) blocking tissue responses (Hubbell, 1995; Wintermantel *et al.*, 1996). Implicit in this consideration is that the specific material architecture (e.g., membrane, gel, matrix, tube) is critical to the tissue-engineering product design and thus influences the choice of biomaterials.

### Barriers: Membranes and Tubes

Design formats requiring cell activity on one surface of a device while precluding transverse movement of surrounding cells onto that surface call for a barrier material.

**STRUCTURE 23.9.** A poly(amide carbonate) derived from desaminotyrosyl tyrosine alkyl esters. This is an example for a group of new, amino acid-derived polymers.

For example, peripheral nerve regeneration must allow for axonal growth and at the same time preclude fibroblast activity that could produce neural-inhibiting connective tissue. Structures such as collagen tubes can be fabricated to yield a structure dense enough to inhibit connective tissue formation along the path of repair while allowing axonal growth through the lumen (S. Li *et al.*, 1992). Similarly, collagen membranes for periodontal repair provide an environment for periodontal ligament regrowth and attachment while preventing epithelial ingrowth into the healing site (van Swol *et al.*, 1993). Antiadhesion formulations using hyaluronic acid, which prevent ingrowth of connective tissue at a surgically repaired site, also work on this concept (Urmann *et al.*, 1991).

## Gels

Gels are used to provide a hydrogel scaffold, encapsulate, or provide a specialized environment for isolated cells. For example, collagen gels for tissue engineering were first used to maintain fibroblasts, which were the basis of a living-skin equivalent (Parenteau, 1999). Gels have also been used for the maintenance and immunoprotection of xenograft and homograft cells, such as hepatocytes, chondrocytes, and islets of Langerhans, used for transplantation (Sullivan *et al.*, 1991; Chang, 1992; Lacy, 1995). Semipermeable gels have been created to limit cell-cell communication and interaction with surrounding tissue and to minimize movement of peptide factors and nutrients through the implant. Injectable biodegradable gel materials that form through cross-linking *in situ* show promise for regeneration of bone and cartilage. Temenoff and Mikos (2000) review a number of injectable systems that demonstrate appropriate properties for these applications. Lee *et al.* (2005) discuss the use of biodegradable polyester dendrimers, highly branched synthetic polymers with layered architectures, to form hydrogels for tissue-engineering applications such as corneal wound sealants. In general, nondegradable materi-

als are used for cell encapsulation to maximize long-term stability of the implant. In the future, however, it may be possible to formulate novel smart gels, in which biodegradation is triggered by a specific cellular response instead of simple hydrolysis.

## Matrices

It has been recognized since the mid-1970s that three-dimensional structures are an important component of engineered tissue development (Yannas and Burke, 1980; Yannas *et al.*, 1980). Yannas and his coworkers were the first to show that pore size, pore orientation, and fiber structure are important characteristics in the design of cell scaffolds. Several techniques have subsequently been developed to form well-defined matrices from synthetic and biologically derived polymers, and the physical characteristics of these matrices are routinely varied to maximize cellular and tissue responses (Fenkel *et al.*, 1997; Langer and Vacanti, 1993; Salem *et al.*, 2002; Hodde, 2002). Examples of engineered matrices that have led to several resorbable templates are oriented pore structures designed for regeneration of trabecular bone (Borden *et al.*, 2003; Lin *et al.*, 2003).

## VI. CONCLUSION

Research in the use of currently available biomaterials and in developing novel bioresorbable polymers has helped to drive the establishment of the field of tissue engineering. Despite a wide range of possible choices, there is a tendency to choose those bioresorbable polymers that have a history of regulatory approval, instead of letting the application guide the choice of material. The latter approach, moreover, may require lengthy and costly polymer development work. Nonetheless, in order to gain the sort of precise control over cell response and cell interactions with surrounding tissues that is expected of tissue-engineering applications, continued research on new bioresorbable polymers will be necessary.

### I. INTRODUCTION

The design and fabrication of biodegradable scaffolds are keystones to advancing the field of tissue engineering and organ regeneration. Similarly, the widespread application of microfabrication strategies has proven to be beneficial both in elucidating complex biological processes and improving cell function through a variety of avenues. Although a wide number of techniques and approaches have been developed to study the behavior of cells and their components *in vitro*, expanding micro-scale functionalities to tissue engineering scaffolds could prove beneficial in controlling cell function *in vivo*. Incorporating micro-scale systems and strategies for tissue and organ regeneration into scaffolds requires the ability to develop advanced microfabrication techniques tailored specifically for biomaterials. This chapter is dedicated to describing current strategies for the microfabrication of biomaterials within the context of realizing an ultimate goal of fabricating biodegradable scaffolds with micron- and nanometer-scale features. In general, these processes and approaches implement modifications to traditional micro-scale fabrication techniques, such as replica molding, soft lithography, and electrospinning, thereby expanding processing capabilities to include either natural or synthetic biomaterials. More

advanced techniques, such as solid free-form fabrication and the production of *in situ* cell-seeded scaffolds, are also reviewed. The next generation of scaffold fabrication will benefit from adapting nascent generalized materials-processing strategies to expand functionality and match corresponding advances in novel biomaterial development.

The design and engineering of suitable biodegradable scaffolds are central to the field of tissue engineering and organ regeneration. Traditional advancements in scaffold fabrication have focused on developing new types of biomaterial systems with more desirable characteristics, such as reduced toxicity or immune response, increased strength, and elastomeric properties. Parallel fabrication strategies have also been improved and developed to accommodate novel biopolymeric systems and to some extent have also been modified to improve and control a similarly defined parameter space, including, for example, biocompatibility, pore size, porosity, and pore connectivity (Murphy *et al.*, 2002). Integrating drug delivery techniques to administer appropriate growth factors or growth factor-encoding plasmids can lead to improved cell and tissue function and in some cases can promote improved tissue function and vascularization of the construct (Lee *et al.*, 2000; Shea *et al.*, 1999). This general approach has been shown to be useful

in the application of designing systems to support the growth of small volumes of simple tissues of primarily one cell type, such as the epidermis, cartilage, and the bladder (Oberpenning *et al.*, 1999). Complex or highly vascularized organs and tissues such as the muscle, liver, and kidney require the integration of many cell phenotypes, where the functionality of the organ is highly dependent on spatially defined microenvironments and subsequent heterotypic cell–cell interactions. While there have been substantial advancements in producing vascularized scaffolds (Levenberg *et al.*, 2005), the inability to produce large volumes of organs is still problematic. Controlling the mechanical, chemical, and spatial cellular microenvironments within a scaffold is essential to designing tissue engineering systems.

The integration of micro- and nanoscale technologies with biology and bioengineering has led to significant advancements in the field of tissue engineering. Probing cells and biological systems with tools that operate at the micron- and submicron-length scales have led to the elucidation of some of the fundamental parameters of the cellular microenvironment that influence cell processes and phenotype. Studying and controlling cell–matrix interactions is also of extreme importance. While the chemistry and biology of cell–matrix interactions have been studied extensively, the topography of this interface also plays an important role in regulating cell function. The extracellular matrix is known to contain nanometer-scale features, which provide cues that influence essential cell functions such as proliferation, migration, and spreading. Numerous synthetic systems with a variety of submicron-scale feature sizes and geometries have been used to study the behavior of cells in response to substrates rich in nanometer-scale topographical cues (Flemming *et al.*, 1999). Cells have also been known to respond to randomly oriented topography such as nano-scale roughness in addition to well-defined substrates with submicron-scale fabricated features. Topographic features on the order of 1 micron or smaller can influence a number of cell functions, including cell attachment, morphology, and directed migration, which are important cellular processes to control in fabricating cell–scaffold constructs. Cell alignment, for example, has been shown to play an important role in developing stronger tissues in the cases of smooth muscle cells, skeletal muscle, and fibroblasts. Topography has also been shown to influence the gene profile (Dalby *et al.*, 2003b), including the up-regulation of fibronectin mRNA levels in fibroblasts (Chou *et al.*, 1995). The generalized reaction of cell to topography has been extensively reviewed elsewhere (Curtis and Wilkinson, 1997, 1998; Flemming *et al.*, 1999).

An understanding of the interactions between cells and chemical, topographical, and spatial microenvironments is an important aspect for the rational design of tissue engineering systems. The corpus of work performed in the field of microfabrication for tissue engineering has focused primarily on studying cellular interactions in two dimensions.

Translating the systems and techniques developed to control cell function in two dimensions must be expanded and applied to demonstrate similar control in three-dimensional scaffolds in order to utilize tissue engineering as a viable therapeutic option. The current paradigm of biomimicry in the fabrication of tissue engineering scaffolds requires the ability to control the cellular environment on a micron and submicron level. A wide range of top-down and bottom-up processes have been developed to meet the corresponding increase in demand of micro- and nanometer-scale precision in developing tissue and organ regeneration systems. This chapter focuses on the design and fabrication of tissue-engineering scaffolds with micron- and submicron-scale features by surveying the current state of the art in a wide range of systems and approaches.

## II. ADAPTATION OF TRADITIONAL MICRO-SCALE TECHNIQUES FOR SCAFFOLD FABRICATION

Photolithographic-based processes originally employed in the microfabrication of integrated circuits, used in combination with techniques such as replica molding of polymers and patterning of biomolecules, function as the primary method for studying the effect of microenvironmental parameters on cell function. Manipulating cell geometries on the micron scale can lead to precise control over cell functions such as differentiation, migration (Jiang *et al.*, 2005), proliferation, and cell fate (Chen *et al.*, 1997). In addition to spatially dependent signals in homogeneous cell populations, heterotypic cell–cell interactions have been proven critical in controlling cell function (Bhatia *et al.*, 1999). Because nearly all functional tissues are heterotypic, defining the spatial organization of multiple cell types precisely has been shown to lead to improved function of said tissues. As the complexity of the organ increases, so does the importance of defining appropriate cell–cell interactions precisely. The following section is dedicated to describing the application of traditional microfabrication techniques to the fabrication of tissue-engineering scaffolds.

### Photolithographic-Dependent Processes

Photolithography for use in silicon micromachining and soft lithography is a keystone for developing microfabricated systems for tissue engineering with precise spatial control of structures. The inherent two-dimensional nature of photolithographic-based systems led to the development of microdevices that interface directly with biomolecules and cells, which has proven useful in the study of cell–matrix and heterotypic cell–cell interactions. Microfabrication of inorganic materials such as silicon and quartz for etching and replica molding of poly(di-methyl-siloxane) (PDMS) has been used extensively for biomedical applications, including biosensors and microfluidic networks (Borenstein *et al.*, 2002; Duffy *et al.*, 1998). While they are biocompatible,

microscale systems constructed using inorganic materials found in traditional microfabrication techniques are inherently limited to *in vitro* applications such as diagnostic systems. Nevertheless, microfabricated silicon or replica-molded PDMS molds produced from soft lithography can also be interfaced directly with natural or synthetic polymers to create microsystems for biomedical applications. Biodegradable polymers can be cast onto microfabricated molds to produce structures on substrates with feature resolutions as small as 20 nm. Thermoplastic biopolymers such as poly( $\epsilon$ -caprolactone) (PCL), poly(L-lactic acid) (PLA), and poly(L-lactic-co-glycolic acid) (PLGA) have been processed in this manner for various biomedical applications, including tissue engineering scaffolds and devices for controlled drug release (Armani and Liu, 2000; Richards-Grayson *et al.*, 2003). Melt-casting, solvent-casting, and hot-embossing can all be employed to attain well-defined feature geometries in polycrystalline or amorphous synthetic biomaterials. Composite materials featuring various synthetic biodegradable materials or inert metals such as gold and silicon have been fabricated for applications in drug delivery (Santini *et al.*, 1999). Similar processes can be adapted for fabricating tissue-engineering scaffolds with conductive polymers for potential in nerve regeneration applications (Schmidt *et al.*, 1997). Thermoset biomaterials, including cross-linked elastomeric networks such as poly(glycerol-sebacate) (PGS) (Wang *et al.*, 2002) and poly(1,8-octanediol-co-citric acid) (POC) (Yang *et al.*, 2004), require that the material be set into a given shape when initially molded, followed by a chemical or physical cross-linking process. Therefore, processing of such materials may require the use of a sacrificial mold release layer consisting of a biologically benign material to prevent adhesion of these aggressive materials to the mold used during the final polymerization. Dilute sucrose solutions, which are typically used to prevent flocculation and coagulation in microparticle formulations, can be used to create thin films for aid in mold release of films while maintaining the fidelity of submicron-sized features (Bettinger *et al.*, 2006a).

Fabricating tissue engineering scaffolds with therapeutic potential requires the expansion of two-dimensional microfabrication techniques to enable the production of three-dimensional systems. Lamination techniques are suitable for the integration of multiple micromolded biopolymer layers into a complex three-dimensional structure. Soft-lithography techniques have been used to fabricate molds with PDMS for use in the solvent casting of concentrated PLGA solutions or embossing of solid PLGA to produce microfabricated layers (King *et al.*, 2004; Vozzi *et al.*, 2003). Multiple thin layers of PLGA on the order of hundreds of microns in thickness can be laminated together to form substantially thick structures. Bonding of micromolded PLGA has been accomplished by applying pressure and elevated temperatures to produce scaffolds in a variety of hierarchical geometries. The processing window to bond

layers and maintain microfluidic structures is heavily dependent on the temperature and the duration of bonding. The combination of heat and pressure results in a fusion of PLGA molecules at the points of contact, leading to a nearly indistinguishable interface. An alternative method of lamination of synthetic biopolymers can be achieved by solvent fusion at the interface. These processes, while originally demonstrated in PLGA systems, can be applied in principle to any thermoplastic polymer with similar physical properties. Chemical bonding between interfaces can also be employed to laminate multiple layers together. Cross-linking of thermoset polymers involving an additional polymerization step has been used to produce three-dimensional networks by laminating multiple microfabricated layers (Bettinger *et al.*, 2006b) (see Fig. 24.1). Altering the processing conditions of the thermoset layers used in lamination can vary material properties, such as cross-linking density, which directly influences subsequent properties, such as mechanical moduli, ultimate tensile strength, adhesiveness, and permeability. Fine-tuning the adhesiveness is especially critical in developing lamination processes able to preserve the microstructures within the layers. The selective implementation of chemical reagents such as (1-ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride) (EDC) and *N*-hydroxysuccinimide (NHS), an established chemical route for bioconjugation of amines to carboxylates, could also theoretically be employed to laminate polymeric sheets. One potential challenge for expanding the use of biodegradable microfluidic networks is the incorporation of proteins such as growth factors. Microfabrication processes often generate nonphysiological conditions through the use of high temperatures or the inclusion of organic solvents, both of which would denature and eliminate the bioactivity of most proteins or lead to low cell viabilities.

One typical application of microfabricated biopolymers is the development of biodegradable microfluidic devices (Bettinger *et al.*, 2006b; King *et al.*, 2004). Polymeric microfluidic systems provide a platform technology for the development of microfluidic scaffolds, which are advantageous for traditional porous scaffolds, due to the potential for rapid perfusion and improved control over the microenvironment. These systems have been seeded with a variety of cell types, which maintain their long-term function and viability via perfusion. Furthermore, after fabrication and *in vitro* cell seeding, these devices have the potential for host implantation. One could also envision the expansion of biodegradable polymeric microfabrication to produce implantable diagnostic systems, such as temporary, resorbable biosensors. Microfluidic devices have also been fabricated from calcium alginate hydrogels, another versatile material used extensively in drug delivery and tissue-engineering applications (Cabodi *et al.*, 2005). In this reported method, calcium alginate gels are patterned using an adapted soft-lithography technique, which are able to

**FIG. 24.1.** Application of traditional replica-molding techniques to microfluidic scaffolds. **(A)** Two-dimensional layouts can be designed in arbitrary patterns using graphics programs such as AutoCAD 2000. Two example layouts are shown (scale bar is 5 mm). Insets show detailed schematics of the representative microstructures used in each two-dimensional layout. **(B)** SEM of micromachined silicon “negative” masters designed for polymer replica molding of microfluidic networks. **(C)** Replica-molded poly(glycerol sebacate) layer of silicon master in B. Replica molding of microstructures has also been developed for numerous other materials, including PLA, PLGA, alginate hydrogels, and photo-cross-linkable biomaterials (see text). **(D)** SEM cross sections of three-dimensional PGS microfluidic device. **(E)–(F)** Composite fluorescent micrographs of devices after flowing rhodamine and DAPI solutions to demonstrate the patency of multilayer microfluidic devices (scale bars in B–F are all 200 microns). Multiple fluids can be perfused into various microfluidic layers without mixing. Reproduced from Bettinger *et al.* (2006b) with kind permission of Wiley Interscience and John Wiley & Sons, Inc. Copyright 2006. All rights reserved.

produce microchannels with cross-sectional areas between  $100 \times 200$  microns and  $25 \times 25$  microns. The channels are sealed via chemical cross-linking by first chelating calcium from each of the faces to remove cross-links, laminating the hydrogel slabs together, and then inducing chemical linkages via the addition of calcium chloride. Flowing solutions of both small molecules and high-molecular-weight compounds results in a variety of possibilities of transient concentration profiles throughout the hydrogel network. Parameters such as flow geometry, volumetric flow rate, concentration of solute, molecular weight of solute, and cross-linking density of hydrogel can be adjusted to control the spatial and temporal coordinates of concentration. The utility of such a system lies in the ability to potentially perfuse the ambient hydrogel network, which would presumably be housing seeded cells, to enhance nutrient supply and waste removal. This application would be especially useful for highly metabolically active cells, such as hepato-

cytes. Microfluidic systems have also been fabricated via photo cross linking of acrylated PCL and PLA hybrid polymers (Leclerc *et al.*, 2004). These systems have been fabricated using an adapted soft-lithography technique as well, in which a PDMS mold is used to form microchannels during the UV-initiated photopolymerization process. The mold is removed immediately after cross-linking, and the microfabricated material remains. Human umbilical endothelial cells (HUVECs), fibroblasts, and HepG2, a human hepatocarcinoma cell line, have been cultured on microstructures fabricated in this manner.

Modification to traditional photolithographic techniques can be used to expand the set of potential fabrication methods to produce more complicated systems. The creation of three-dimensional structures is a desirable thrust for use as masters in the fabrication of advanced microscale systems, such as microfluidic systems with complex layouts or biomimetic structures. The formation of three-

**FIG. 24.2.** A 3D master pattern to cast a microfluidic mimic of a vascular network. The gaps in the original pattern determine the height of each section. **(a)** The original two-dimensional conductive pattern — a gold film patterned onto a silicon nitride covered wafer; **(b)** SEM image of the resulting 3D structure; the smallest lines are 10 μm high, the tallest are 80 μm. The deposition originated from the left side of the image. Reproduced from Lavan *et al.* (2003) with kind permission of Wiley Interscience and John Wiley & Sons, Inc. Copyright 2003. All rights reserved.

dimensional structures via traditional two-dimensional photolithographic techniques requires numerous masks, multiple photolithographic steps, and precise alignment between each cycle of photolithography and etching. These complications lead to increased cost and a reduction in speed. A convenient method for rapidly producing three-dimensional structures using a modified electroplating technique can circumvent many of the previously defined issues (Lavan *et al.*, 2003) (see Fig. 24.2). First, a patterned substrate consisting of an array of conductive islands with a precise, predefined lateral arrangement is patterned on an insulating substrate through a single lithographic metal patterning step, such as gold liftoff. A wire lead is connected to a single conductive island and a corresponding counter-

electrode, respectively, and placed in a plating solution of a conductive material such as nickel or poly(pyrrole), an electrically conducting biocompatible polymer (George *et al.*, 2005). At the start of electrodeposition, material is plated only on the island initially in contact with the lead. As electroplating continues, the conductive material grows laterally, spanning the insulating regions, and vertically, increasing the feature height, at rates that are governed by the plating material and processing parameters. When the conductive material bridges an insulating region and comes in contact with a nearby conductive island, material is then plated on both patterns. Due to the lag in electroplating imparted by the insulating region, the structures plated earlier in the first structure will be taller and wider than features plated on subsequent conductive regions. This process of bridging insulating gaps is repeated as electroplating continues, where the resulting differences in feature height and width of subsequent features is governed by the lateral spacing of the conducting islands and the intrinsic anisotropy of plating velocities of the electrodeposited material. In addition to being helpful for creating a wide variety of MEMS components and devices, this technique can be used to fabricate masters for the production of microfluidic vascular scaffolds with channels that possess aspect ratios of the order of unity. This technique may serve to overcome the issue of connecting macroscopic fluid-handling systems with microscale fluidics by eliminating the presence of high-aspect-ratio microchannels at the inlet and outlet, which create difficulty in establishing patency. Creating a microfluidic master with similar flow characteristics using a traditional process consisting of a single photolithographic step would lead to undesirable feature geometries with extremely high aspect ratios that can exceed 1 : 500.

### Electrospinning

Photolithography is a time-consuming and expensive method to produce well-defined microfabricated features with accurate spatial characteristics. Alternative methods to photolithographic-based processes allow the fabrication of biomaterial surfaces with nanoscale topography, which can improve cell functions such as adhesion, migration, and proliferation. Electrospinning is a convenient method for producing arrays of loose fibrous networks containing rich nanometer-scale texture with individual fiber diameters on the order of hundreds of nanometers. The electrospinning process draws a continuous narrow stream of material from a reservoir of polymer melt or solution to a collecting plate, where the material accumulates, producing the fibrous mat. This is accomplished by inducing charge buildup on the surface of the solution through the application of strong voltages. When the voltage is sufficiently strong, the electrostatic potential overcomes the energy associated with surface tension of the bulk material at the orifice, and the solution is accelerated toward the grounded collector. As the

polymer solution is propelled to the collector, the solvent evaporates, resulting in a continuous stream of ultrathin fibers. Electrospinning has been used to fabricate fibrous scaffolds using a variety of natural materials, such as silk fibroin (Jin *et al.*, 2002), collagen, polypeptides, and synthetic polymers such as PLGA, PCL, poly(vinyl alcohol) (PVA), and poly(ethylene oxide) (PEO). Ceramics and composite fiber networks have also been produced using electrospinning techniques (Li *et al.*, 2003). The diameters of individual fibers can range from approximately 30 nm to 1 micron, and they are varied by controlling the properties of the solution, such as polymer concentration, viscosity, and conductivity, while also carefully defining electrospinning parameters, such as the applied voltage. Nanofibrous scaffolds produced by electrospinning typically result in a thin three-dimensional film of nonwoven mesh consisting of randomly oriented fibers. These mesh constructs can then be laminated together by heating the scaffold to temperatures slightly above the melting point of the polymer or by solvent dissolution and melding. These processes produce fiber bonds at the points of contact between the fibers and result in a cross-linked network. Although random-fiber mats are useful in producing surfaces with rich texture and topography, improving the utility for electrospun materials in tissue engineering is dependent on developing processes to better control the large-scale fiber alignment. Nanofibrous systems with aligned fibers have also been synthesized by using a rotating drum as a collector (Xu *et al.*, 2004) or, in the case of PLGA, by annealing the fibrous network after applying mechanical forces (Zhong *et al.*, 2003). Fabricating topographically rich scaffolds with aligned nanofibers can exploit the contact guidance response in cells and lead to engineered cell functions, such as directed motility. Detailed processes and applications concerning electrospinning nanofibrous scaffolds have been reviewed extensively elsewhere (Ma *et al.*, 2005).

### Laser Patterning of Biodegradable Polymers

Laser micromachining presents a method for rapid production of micro-scale features without the use of expensive photomasks. Microfabrication of polymeric substrates using ablation is typically performed with UV laser types such as excimer, argon-ion, fluorine, helium-cadmium, metal vapor, and nitrogen. Polymers are etched when the energy of the incident photoelectron is large enough to dissociate chemical bonds directly while imparting little thermal damage to the nonmachined regions. Geometries such as holes and trenches can be produced in biodegradable substrates with minimum feature sizes of approximately 10 microns in polymers such as PVA, PCL, and PLA (Kancharla and Chen, 2002). Laser ablation, while proven directly useful for micromachining, can simultaneously functionalize surfaces that have undergone laser treatment. Laser irradiation can lead to the incorporation of nitrogen or oxygen molecules, thereby creating functional groups such as amines

and carboxylic acids. These functionalities can serve as precursors to surface modifications such as covalent linkages of peptides or non-biofouling agents. Laser ablating techniques can be used in combination with nanoparticles for the rapid fabrication of polymer substrates with arrays of nanoscale features with dimensions much smaller than the wavelength of light. One approach, termed *nanosphere lithography*, uses an ordered template of nanometer-scale particles as a method to focus laser irradiation that is directed at the surface of the polymer substrate to create arrays of nano-scale pits (Lu *et al.*, 2003b). A solution of silica nanoparticles is deposited onto the surface of the substrate. Upon evaporation of the solvent, surface tension effects largely outweigh the thermal energy ( $kT$ ), which produces in an energetically favored packing event. The result is spontaneous ordering of nanoparticles into a hexagonal closely packed configuration. A nearly identical method can serve to create ordered micro-scale sacrificial templates for use in porogen-leaching scaffold fabrication, which is described in the upcoming section on micro-scale templates and self-assembly. The ordered silica nanoparticles focus the UV irradiation on illumination, causing localized ablation, which can produce features, such as pits, as small as 30 nanometers in diameter. The size and geometry of the features can be varied by adjusting processing parameters, including the diameter of the nanoparticles, the wavelength of the laser, the energy of radiation, and the angle of incidence of the irradiation (Kosiorrek *et al.*, 2005). Nanosphere lithography provides a convenient method for creating large ordered arrays of feature dimensions that would otherwise be too slow, expensive, and, in the case of features on the order of 10 nanometers, impossible using traditional photolithographic methods. While the set of potential feature geometries and sizes is inherently limited by the top-down nature of nanosphere lithography processes, the arrays of materials that can be used are fundamentally similar to those involved in laser ablation. Nonetheless, this method could be useful in engineering polymeric substrates to study or enhance cell-matrix interactions by providing nanotopographic signals.

## III. THREE-DIMENSIONAL SCAFFOLDS WITH MICRO-SCALE ARCHITECTURE

The behavior of cells in three-dimensional microenvironments is well known to differ vastly from cells grown on two-dimensional surfaces (Cukierman *et al.*, 2002). This fact has prompted the drive to design and fabricate tissue engineering scaffolds that provide a suitable three-dimensional structure to support native cell function. The gravitation toward three-dimensional scaffolds has presented significant challenges in integrating control over spatial distribution and geometries of micron-scale structures. However, average scaffold geometry characteristics can be designed by controlling parameters such as polymer

composition in conjunction with physical processing parameters. This technique has been accomplished using a variety of material processing approaches, some of which are presented in the following section.

### Polymer Demixing and Microphase Separation

Capitalizing on characteristic phase separation behavior of polymer solutions and polymer blends is another route toward developing systems for use as scaffolds with ordered features on the micron- and sub micron-length scale. The microphase morphology and characteristic length scale of features in polymer blends can be tuned by adjusting thermodynamic-dependent parameters such as the composition of the blend and kinetic parameters such as temperature, which govern the potential for spinodal decomposition and subsequent polymer demixing. The most commonly observed microphase morphologies are spherical, cylindrical, and lamellar, although numerous other classifications of morphologies have been observed in a variety of systems including block copolymer blends (Tang *et al.*, 2004). Modification of these bulk polymer blends via selective polymer etching or dissolution could lead to the potential for development of ordered tissue engineering scaffolds with micron-scale geometries that are physiologically relevant for numerous applications. The phenomenon of polymer demixing and phase separation can also be adapted to the development of thin films as a method for chemical-induced topological modification. For example, partially compatible polymer blends spin-coated into a thin film can produce topographically rich surfaces with structures of rounded pillar morphologies on the order of 100 nm in height and width (Dalby *et al.*, 2003a). Surfaces with polymer demixed nanotopography have been shown to affect the growth and spreading of human fibroblasts, for example. Further refinement of a similar process could lead to the development of integrating topographically rich surfaces with complex three-dimensional porous structures that enable the uniform presentation of topographical cues throughout the spatial extent of the scaffold. Electrospinning polymer blends provides another route for fabrication of nanometer-scale fibers with cocontinuous phase separation by using ternary mixtures of PLA and poly(pyrrolidone) (Bognitzki *et al.*, 2001).

Freeze-drying presents another possible route to producing scaffolds with micron-scale features (Whang *et al.*, 1995), although the control of spatial locations and distributions is reduced. A typical freeze-drying procedure begins with the addition of water to a solution of PLGA in methylene chloride. The solution is homogenized, poured into the appropriate mold, and then quenched rapidly at approximately  $-180^{\circ}\text{C}$  using liquid nitrogen. This rapid-quenching step leads to immediate phase separation within the scaffold, which is then freeze-dried to remove the water and residual solvent. This process can produce scaffolds with pore sizes in the range of 15–35 microns, which can be as

small as one order of magnitude smaller than the standard PLGA scaffolds fabricated using the traditional porogen-leaching process. A similar method has been demonstrated in the production of porous PLA scaffolds with incorporated bioactive molecules (Lo *et al.*, 1995). The potential advantages of this and similar systems for tissue-engineering applications are numerous and somewhat obvious. Drug release experiments suggest that slightly elevated temperatures in the range of  $55^{\circ}\text{C}$  to  $85^{\circ}\text{C}$  and the presence of organic solvents during preparation of these scaffolds has shown to impact slightly negatively the activity of the released molecules. However, in terms of engineering the microscale structure of these scaffolds, precise control of pore size, geometry, and interconnectivity is severely limited by the deferral to equilibrium processes in the preparation of such scaffolds. This leads to control of the averaged scaffold features, which can be manipulated through adjusting processing parameters.

### Micro-Scale Templates and Self-Assembly

Porogen leaching is a common approach to developing large, three-dimensional, porous scaffolds. In this established technique, the scaffold material is incorporated with a chemically or physically incompatible porogen. Upon scaffold fabrication via a process such as solvent evaporation or chemical and physical cross-linking, the porogen is selectively removed. One consequence of this method of fabrication technique is the high degree of porosity (typically in the range of 90% or higher), which is necessary to achieve an interconnected network for random porogen organization. Scaffolds with extremely high porosities are advantageous for tissue engineering metabolically active tissues by allowing for more rapid diffusion of nutrients and removal of waste products. High porosities also provide large surface areas per volume to allow cell attachment and proliferation. However, the mechanical properties of highly porous networks are severely compromised, including a dramatic reduction in the relative stiffness of the porous and solid scaffolds,  $E_{\text{cellular}}$  and  $E_{\text{solid}}$ , respectively, with increasing porosity,  $P$ . This relationship is proportional to a geometrically defined constant through the following equation:

$$\frac{E_{\text{Cellular}}}{E_{\text{Solid}}} = C(1 - P)^2 \quad (24.1)$$

Reducing the porosity required for interconnection can be obtained through ordered assembly of uniform, micron-scale, spherical, colloidal particles (Stachowiak *et al.*, 2005). Physical templating through geometric constraints can produce scaffolds that exhibit dramatically increased stiffness and improved toughness, which has been shown to affect cell behavior, when compared to randomly assembled porogen structures. This fabrication technique has been employed for creating hydrogel networks with increased moduli using a porogen network consisting of ordered microspheres. Poly(methyl-methacrylate) (PMMA)

microspheres of diameters ranging from 20 to 60 microns in a 30 : 70 water/ethanol mixture were deposited under physical perturbation to enhance characteristic hexagonal close-packed ordering. A solution of low-molecular-weight PEG dimethacrylate (PEG-DMA) modified with adhesion-promoting peptides was administered to the template and irradiated with UV to induce cross-linking of the scaffold. The PMMA porogen network was etched with acetic acid, leaving a porous hydrogel network that was shown to support the attachment and migration of NR6 fibroblasts. Using an ordered sacrificial pore structure has demonstrated an increase in stiffness by up to several orders of magnitude, to the range of 10 kilopascals, which is comparable to that of soft tissues. In principle, this process could be applied to any number of polymer-porogen systems that exhibit physical properties that permit removal of the sacrificial phase, such as relative selectivity in dissolution, degradation, or differential melting points.

Ordered template assembly can also be achieved through self-assembly of biomolecules such as proteins and DNA. Self-assembly of peptide systems into supramolecular structures requires the rational incorporation of specific and selective interactions among the amino acid building blocks. The resulting structures can be tuned by manipulating amino acid sequences that provide the appropriate combinations of properties, such as charge and residue hydrophilicity. Beta-sheet structures can be produced by incorporating peptides with one hydrophobic surface and one hydrophilic surface in an aqueous solution. The hydrophobic surfaces become shielded while the charged hydrophilic residues remain in contact with the aqueous environment in an organization event that is similar in nature to *in vivo* protein folding. The hierarchical structure of this assembly process is evident by the ability to synthesize structures on the order of 30–100 nanometers by virtue of single-peptide building blocks with lengths on the order of 1 nanometer. This technique has been utilized with natural amino acid sequences to produce a wide range of structures with nanometer-scale features, including modified surfaces, filaments, and fibrils and peptide nanotubes for a variety of applications, including tissue engineering and drug delivery (Zhang, 2002). Macromolecular structures can also assemble to produce stable networks of nanometer-scale fibers. Self-assembling peptide networks have been used to support three-dimensional cell culture systems and feature fibers diameters on the order of 10 nm, with pore sizes between 200 and 500 nm (Zhang, 2003). Reversible hydrogel structures have also been synthesized by engineering synthetic tri-block peptide structures (Petka *et al.*, 1998). Peptide constructs have been used to produce ordered peptide nanotubes, which may include other materials for various applications. In one approach, amyloid fiber peptides, the precursors that form prions, which eventually produce the onset of Alzheimer's disease, can self-assemble to produce silver nanowires on the order of 100 nm in diam-

eter (Reches and Gazit, 2003). Although the original intention of studying these processes was to aid in the assembly of inorganic materials such as metallic nanowires for applications in electronics (Scheibel *et al.*, 2003), similar approaches could be applied to develop advanced tissue engineering constructs. One can envision the development of a two-phase scaffold that may incorporate a functional inorganic material or organic polymer in conjunction with a peptide shell that could introduce additional desirable properties. One potential limitation of this class of materials for tissue engineering applications is the extremely small characteristic length scale of peptide self-assembly. It may be necessary to fabricate tissue engineering constructs with feature definition that ranges over a wide range of length scales. Although nano-scale features can modulate biological function on the cellular level, controlling the structures of scaffolds on the length scale of hundreds of microns or larger may be required for some tissues to create biomimetic macroscopic geometries, improve mechanical strength, or optimize porosity connections to enhance nutrient transport and waste removal. Expanding the operable length scale of this technique could lead to the advancement in meso-scale assembly of larger structures with feature sizes on the order of tens of microns, which may result in a tissue engineering microenvironment that better supports spatially dependent cell processes such as migration, proliferation, and matrix remodeling. Combining template or self-assembly techniques with other scaffold fabrication techniques with much higher minimum resolutions may be a near-term solution to controlling scaffold features and geometry across several orders of magnitude.

#### IV. THREE-DIMENSIONAL SCAFFOLD ASSEMBLY

The motivation for scaffold design must be focused on the ability to create scaffolds with predefined and precisely controlled unit cell geometries to enable optimization of pore structure that can accommodate constraining parameters such as mechanical properties and nutrient transport. Controlling pore structure on a micron scale requires the recruitment of computational topology-design tools. The general field of rapid prototyping forms three-dimensional objects from computer-generated solid or surface models. Programs such as computer-aided design (CAD) coupled with the ability to fabricate arbitrary and complex three-dimensional structures through the use of rapid prototyping and solid free-form fabrication (SFF) techniques have allowed the production of designer scaffolds with predefined microarchitecture. One of the major limitations in microfabricated scaffolds has been the inherent limitation of photolithography to two-dimensional micropatterning. Although some photolithographic processes can be stepped to create three-dimensional structures, SFF techniques, through the implementation of controlled deposition using

computer programs, do not require the use of multiple photomasks or an alignment step between layers. Systems that can freely incorporate controlled microfabrication processes in the  $z$ -direction have complete control over the microscale geometries and the relevant resulting macroscopic properties. A number of fabrication routes that control the fabrication in three dimensions have been devised to fabricate many classes of materials, including polymers, composites, and ceramics (see Fig. 24.3). Of particular interest is controlling the mechanical moduli of the scaffold to match the range of moduli found in either soft tissues (0.5–350 MPa) or hard tissues (10–1500 MPa). The following section outlines the current state of the art of SFF and outlines potential advancements and applications for use in scaffold fabrication.

### **Stereolithography, Selective Laser Sintering, and Three-Dimensional Printing**

Stereolithography (SLA) and selective laser sintering (SLS) are SFF techniques that use a laser-based curing device to photopolymerize liquid monomers or to sinter powdered materials, respectively. Both processes begin by designing a three-dimensional structure via CAD, which is then converted into geometrically patterned two-dimensional slices of approximately 100 microns in thickness. A computer-controlled servo mechanism transmits information to the scanning laser and guides the location within the  $x$ - $y$  plane, selectively bonding the material to form the structure. The build platform is then stepped down the same distance as the slice thickness and a new slice is scanned. SLA selectively polymerizes material for a vat of photopolymeric solution in a layer-by-layer process. SLA has been used to fabricate scaffolds from poly(propylene fumarate) and diethyl fumarate mixtures for hard tissues, including the repair of bone defects (Cooke *et al.*, 2002). PEG-DMA scaffolds incorporated with PLGA microparticles have also been fabricated for use in the tissue engineering of soft tissues (Lu *et al.*, 2003a). One previous limitation of SLA-based processes had been the inability to fabricate structures, such as scaffolds, that were large enough for clinical applications. This limitation has been overcome with the work of Cooke *et al.* because relevant length scales for repairing critical-sized bone defects can be fabricated using SLA. SLS, an SFF method that is operationally similar to SLA, selectively bonds material from a powder bed using a CO<sub>2</sub> laser that is directed on a powder bed of material. The laser is scanned across the surface and sinters polymers or composites in a preprogrammed pattern for each layer. Low compaction forces during fabrication in SLS lead to highly porous structures. SLS has been employed in the fabrication of scaffolds using calcium phosphate, PLA, PCL, and poly(ether ether ketone).

The spatial resolution and minimum feature size of SLA and SLS are governed by the laser spot size in the  $x$ - $y$  plane and by the step size in the  $z$ -dimension. Laser spot sizes on

the order of 250 microns are commonly attainable, while spot sizes as low as 70 microns have been achieved for specialty systems. Feature resolution in the  $z$ -axis are theoretically limited by the precision of the mechanical stepping system that governs the slice thickness and is typically no smaller than 100 microns. In general, reducing feature resolution and slice thickness in SLA and SLS processes results in a dramatic decrease in the production speed, which prompts the need to solve the engineering optimization problem to balance the benefits of these two fabrication characteristics. Variations of SLA processes could overcome the limitations due to slice thickness. Cross-linking of biomaterials via multiphoton excitation could also provide an efficient method of three-dimensional scaffold microfabrication. Multiphoton excitation cross-linking using UV has been applied to forming three-dimensional matrices of a wide range of polymers and bulk protein formulations, such as collagen, laminin, fibronectin, polyacrylamide, bovine serum albumin, alkaline phosphatase, and various blends of these (Basu and Campagnola, 2004b). The distribution of intensity of irradiation in the  $z$ -direction theoretically could reduce the minimum feature sizes in this axis to approximately 20 microns or smaller. Remarkably, protein matrices fabricated via this method have been shown to remain active in this polymer matrix environment (Basu and Campagnola, 2004a). Further pursuit of this technology could lead to the rapid and efficient fabrication of three-dimensional structures using a wide variety of biomaterials while simultaneously maintaining delicate conditions that can preserve biological activity.

Three-dimensional printing (3DP) is similar in practice to that of SLA and SLS, in that a three-dimensional object is fabricated one two-dimensional slice at a time using a stepping system. One exception is that 3DP utilizes inkjet printer technology to control the deposition of a chemical binder and to selectively fuse material in a powder bed in order to create the object. Drug delivery and tissue-engineering devices have been fabricated from PEO, PCL, and PLGA using 3DP. However, any biological material could be fabricated in principle using 3DP given the selection of an appropriate chemical binder. The resolution of objects created using 3DP varies with the complexity of the object. Lines 200 and 500 microns in width have been produced using 3DP of polymer solutions and pure solvent, respectively. Feature resolutions of approximately 1 millimeter are more likely for complex geometries. One significant limitation in the application of 3DP for scaffolds is the addition of the chemical binder. Even if the composition of the chemical binder itself is found to be nontoxic and biocompatible, the introduction of cytotoxic organic solvents such as chloroform and methylene chloride is undesirable. Post-fabrication efforts to remove residual solvent, such as vacuum drying, are not completely effective; therefore the issue of cytotoxicity in 3DP-fabricated scaffolds remains.

**FIG. 24.3.** Schematics of SFF systems categorized by the processing technique. **(a, b)** Laser-based processing systems include the stereolithography system, which photopolymerizes a liquid **(a)** and the SLS systems, which sinter powdered material **(b)**. In each system, material is swept over a build platform that is lowered for each layer. **(c, d)** Printing-based systems, including 3D printing **(c)** and a wax-printing machine **(d)**. 3DP prints a chemical binder onto a powder bed. The wax-based system prints two types of wax material in sequence. **(e, f)** Nozzle-based systems. The fused-deposition modeler prints a thin filament of material that is heated through a nozzle **(e)**. The Bioplotter prints material that is processed either thermally or chemically **(f)**. ### Fused-Deposition Modeling

Fused-deposition modeling (FDM) is another method for SFF that has been employed in the fabrication of three-dimensional scaffolds. FDM uses a layer-by-layer deposition technique, in which molten polymers or ceramics are extruded through a nozzle with a small orifice, which merges with the material on the previous layer. The pattern for each layer is controlled by mechanical manipulation of the  $x$ - $y$  position of the nozzle and can be different or arbitrary for each deposited layer. This technique has been applied to the production of three-dimensional scaffolds using polymers (PCL, high-density polyethylene) and composites (PCL/hydroxyapatite). A modification of FDM, termed *fused deposition of ceramics*, has also been developed for fabrication of scaffolds from B-tricalcium phosphate. FDM processes can achieve pore sizes ranging from 160 to 700 microns, with porosities ranging from 48% to 77%. PCL scaffolds fabricated via FDM have a compressive stiffness ranging from 4 to 77 MPa, which spans the mechanical stiffness for both soft and hard tissues (Hollister, 2005). One of the primary advantages of FDM and related processes is the high degree of precision that can be achieved in the  $x$ - $y$  plane. However, control in the  $z$ -direction is limited and governed by the diameter of the material extruded through the nozzle. Additional limitations, including pore anisotropy and the geometry of pore connectivity, are substantially limited due to the continuous deposition process. The extrusion process limits the types of materials that can be processed and therefore has limited the wide applicability of FDM to scaffold fabrication. FDM is typically limited to synthetic thermoplastic polymers, thereby eliminating many natural biomaterials and thermoset synthetic polymers.

### Microsyringe Deposition

Microsyringe deposition is similar in practice to FDM, in that a polymer is patterned onto a precision-controlled surface using a continuous stream of material via layer-by-layer deposition in order to create three-dimensional structures (Vozzi *et al.*, 2003). Pressure-assisted microsyringe-based deposition (PAM) uses compressed air to eject a solution of polymer in volatile solvent through a narrow capillary needle, which has a diameter of between 10 and 20 microns. Control of the placement of solution in the  $x$ - $y$  plane is controlled by a micropositioning system, which can achieve lateral precisions of 0.1 microns, while the physical dimensions of the structures can range from 5 to 600 microns, depending on various processing parameters. PAM has been used to fabricate three-dimensional microfabricated scaffolds from PLGA, but it could theoretically be expanded to any polymer, synthetic or natural, that is soluble in a volatile solvent. PAM presents several distinct advantages over traditional SFF methods, including dramatically improved spatial resolution and feature dimensions. Traditional SFF processes are known to have minimum resolu-

tions on the order of hundreds of microns or larger and have principal limitations in minimum feature size. PAM also offers a convenient method for fabrication of multiphase scaffolds with micron-scale precision placement of multiple polymers. Low temperatures also allow potential integration systems for controlled release of proteins and other biomolecules to create favorable microenvironments for tissue regeneration.

### Future of Solid Free-Form Fabrication for Tissue Engineering

SFF has been established as a convenient set of methods for use in three-dimensional scaffold fabrication of various materials, including polymers, hydrogels, ceramics, and metallic biomaterials. Rational engineering design coupled with computer-controlled materials-processing techniques has allowed precision fabrication techniques that enable the control over the microarchitecture of three-dimensional porous scaffolds. In the near term, designing scaffolds using SFF techniques allows the possibility of indirectly controlling macroscopic properties, such as the bulk mechanical properties and the permeability for nutrient transport considerations. Controlling the characteristics of pores on the micron scale, such as pore geometry, connectivity, and porosity, can lead to tissue-specific scaffold fabrication. SFF also allows the possibility of fabricating designer scaffolds for patient-specific organ regeneration applications. In general, the concept of made-to-order scaffolds is an appealing endeavor, which could serve currently unmet clinical needs, such as scaffolds for reconstructive surgery. However, the eventual use of tissue engineering scaffolds in general relies on the ability to induce predetermined cellular responses. Although SFF has proven to be useful in engineering bulk properties through hierarchical design, future tissue engineering systems may require scaffolds with features of resolution sizes that are smaller than what is achievable with current SFF methods. Current design and fabrication strategies operate on a length scale of hundreds of microns, which may be too large to control cell-specific function. Consider the example of bone tissue engineering using a porous scaffold. Although optimal pore sizes between 200 and 600 microns have been suggested, empirical data for a number of systems suggest otherwise. For example, no significant differences in bone growth of osteocytes on 3DP PLGA scaffolds with pores of 500 microns and 1600 microns was detected (Roy and Al, 2003; Simon and Al, 2003). Hydroxyapatite scaffolds with pore sizes ranging from 400 microns to 1200 microns were used in a mandibular defect model. No significant differences in bone growth were detected across the range of pore sizes used in this study. These findings are consistent with the experimentally verified notion that the length scales of structures that govern many important cell functions, such as adhesion, migration, proliferation, and differentiation, are on the order of tens of microns or smaller. While the value of controlling macroscopic

properties via hierarchical design should not be fully discounted, current SFF techniques as a stand-alone for scaffold fabrication may not be sufficient for inducing appropriate biological responses. One option for fabricating scaffolds with nanoscale features using SFF is simply to improve the current resolution of the processes, which may prove to be too technically demanding or costly to justify future pursuit. Improving resolution to submicron-scale precision would likely slow fabrication speed and would reduce the upper limit of scaffold volume. Therefore, more near-term advances in this field may stem from the integration of micron and submicron structures as a postfabrication modification for scaffolds produced by SFF. One can envision the possibility of using SFF to fabricate a scaffold with the appropriate macroscopic properties, such as scaffold stiffness and geometry. Next, other techniques for producing smaller features, such as the possible integration of another polymer system, could be applied, such as polymer demixing or freeze-drying. The final result would essentially be a two-phase scaffold, where one phase with features on the order of hundreds of microns governs macroscopic properties that would support tissue-level function, while another phase would feature micron-scale geometries to enhance cell–matrix and cell–cell interactions on the cellular level.

## V. MICROFABRICATION OF CELL-SEEDS SCAFFOLDS

Understanding cell–matrix as well as heterotypic cell–cell interactions, both *in vitro* and *in vivo*, is a critical component in designing tissue engineering systems. Coordinating the placement of cells on scaffolds is a promising method of capitalizing on specific cell–cell interactions that may lead to favorable conditions for tissue formation. However, three-dimensional scaffolds that are postseeded with cells cannot typically retain spatial segregation or control specific cell–cell interactions across multiple cell types. While photolithography-based cell-patterning techniques are a powerful method for controlling such interactions in a two-dimensional microenvironment, these methods translate to three-dimensional systems with much difficulty. Advances in microfabrication of biomaterials and SFF have led to the potential to control the placement of polymers and cells with micron-scale precision. Combining aspects of these existing technologies with a layer-by-layer approach is a promising way to fabricate scaffolds that are preloaded with cells that are spatially controlled in arbitrary geometries. Typical scaffold fabrication techniques often employ harsh conditions, such as cytotoxic solvents or elevated temperatures. Hence, developing novel scaffold fabrication processes that are capable of maintaining viable cells is essential. This limitation also serves to reduce drastically the number of biomaterials that are suitable for such processes. Despite

these challenges, a number of possibilities have been demonstrated using this approach to scaffold fabrication.

### Layer-by-Layer Deposition of Cell-Matrix Components

Microfluidic platforms provide a convenient method for controlling many aspects of the cellular microenvironment, including spatial orientation. One-step cell patterning in microfluidic devices has been used to create cellular arrays for diagnostic purposes. When used in combination with a layer-by-layer assembly strategy, micropatterning and microfluidics have proven useful for the controlled assembly of hierarchical constructs of multiple extracellular matrices and cell types. A microfluidic patterned co-culture system with three cell types has been demonstrated for potential use in vascular tissue engineering applications (Tan and Desai, 2004) (see Fig. 24.4). Endothelial cells, smooth muscle cells, and fibroblasts were each mixed with ECM protein solutions such as collagen, one-to-one mixture of collagen–chitosan, and matrigel and deposited sequentially. The result is a three-dimensional layer of multiple cell types that are each contained in user-defined ECM proteins. First, silicon oxide surfaces were modified with 3-aminopropyltriethoxysilane using vapor deposition to enhance the adhesion of ECM proteins. PDMS-on-glass microfluidic systems were fabricated using the modified silicon oxide surfaces. The two-dimensional layout of the microfluidic network can be designed to dictate the eventual location of the nascent tissue structures. One selected cell–matrix solution is then flowed into the microfluidic network at approximately 2°C, at which point the system is heated to 37°C to induce polymerization of the ECM solution. Subsequent layers of cell–matrix systems can be added in a similar manner. After formation of the co-culture structures, the PDMS layer is removed to allow for further characterization of cell function or matrix properties. The obvious advantage of this process is the use of cell-friendly conditions during fabrication, such as the absence of toxic chemicals such as solvents and photoinitiators and UV irradiation. Designing a process that is free of these potentially cytotoxic components of fabrication can produce higher cell viabilities and improve cell function. Tailoring specific cell–matrix combinations can be engineered to produce optimal conditions that improve the overall performance of cell-seeded scaffolds. The use of one microfluidic system limits the flexibility in patterning multiple cell types in an independent manner. This limitation could be potentially overcome by the use of multiple microfluidic patterning techniques, which has been demonstrated in other systems (Khademhosseini *et al.*, 2005).

### Photoencapsulation of Cell-Scaffold Constructs

PEG hydrogels modified with photoactive acrylate groups (PEG-DMA) have been used extensively for photo-

**FIG. 24.4.** Schematic illustration of our approach using microfluidics to create a 3D hierarchical system for three layers of cells within biopolymer matrices. Reproduced from Tan and Desai (2005) with kind permission of Wiley Interscience and John Wiley & Sons, Inc. Copyright 2005. All rights reserved.

**FIG. 24.5.** Process for formation of hydrogel microstructures containing living cells. The apparatus is assembled, including a pretreated glass wafer with reactive methacrylate groups on its surface and a Teflon base with an inlet and outlet. Once the cells and prepolymer solution are injected, the inlet and outlet are closed and the unit is irradiated with UV light. The resulting patterned hydrogels containing cells are covalently bound to the glass wafer. At this time, a thicker spacer can be used in conjunction with a new mask to add another layer of cells. This process can be repeated multiple times to produce cell–scaffold constructs in a hierarchical manner. cross-linkable systems for drug delivery and tissue engineering. Masks typically used for photolithography in traditional microfabrication processes can be used in combination with PEG-DMA solutions to pattern hydrogel structures with micron-scale resolution. In one reported

method, multiple steps of micropatterned photopolymerization processes can be coupled to produce three-dimensional cell matrix structures with micron-scale resolution (Liu and Bhatia, 2002). Silicon dioxide substrates were first functionalized with 3-(trimethoxysilyl)-propyl

methacrylate to allow for covalent bonding of hydrogels. Thin layers of solutions of PEG-DMA hydrogel with HepG2 cells were applied to the functionalized surface and exposed to UV irradiation through a photomask. The substrate is washed to remove the un-cross-linked regions and is stepped in the *z*-direction using a thicker silicone spacer (see Fig. 24.5). This process can be repeated using arbitrary suspensions of cells in PEG-DMA solutions to create additional micropatterned layers. Photopolymerization of cell-encapsulated hydrogels in a layer-by-layer technique provides the flexibility of patterning cell layers in arbitrary geometries. PEG-DMA molecules modified with specific peptides that promote cell functions such as adhesion and migration can be integrated into the scaffold with ease. Furthermore, variables of peptide-modified PEG hydrogels, such as peptide sequences and concentration, can be optimized and incorporated given the tissue of interest. The result is a flexible hydrogel scaffold fabrication strategy that can be used to control the microenvironment of multiple cell types while simultaneously governing the spatial configuration with micron-scale precision. One drawback of such a system is the use of potentially cytotoxic photoinitiators in combination with UV irradiation as a means of creating microstructures. In the reported method, the viability of cells, as measured by MTT assay, is reduced in a dose-dependent manner as the time of UV exposure and concentration of acetophenone photoinitiator was varied between 0 and 60 seconds and 0 and 3 mg/mL, respectively. Another factor that may limit the utility of microfabricated cell-seeded scaffolds using photo cross linkable hydrogels is the maintenance of pattern fidelity of small features with a high degree of precision. While the resolution of features greater than 200 microns is maintained at approximately 10% of the feature size, the resolution is greatly increased as the feature size is reduced below 100 microns. The actual dimensions of features can be increased up to 200% larger than the feature sizes on the photomask, where the ratio is dependent primarily on the exposure time. One mechanism that might explain the increase in feature size is the inherent swelling nature of PEG hydrogels. Other possibilities may be the rapid migration of photoreactive species within the hydrogel during polymerization, which would lead to an overall deficiency in producing features smaller than 50 microns with tight resolution. Although this process has been adapted for the fabrication of PEG hydrogels, it could be expanded to other types of polymeric systems. The design criteria for such future systems are strict and would require a biocompatible, biodegradable, photo cross linkable, water-soluble polymer.

SFF techniques have demonstrated great promise in the design and fabrication of customizable tissue engineering scaffolds. Postseeded cell scaffolds, fabricated via SFF or other methods, limit the attachment of cells to the surface of the scaffold alone, which results in relatively low cell densities. Combining aspects of stereolithography (SLA)

with cell-polymer solutions allows for the possibility of incorporating cells directly in the scaffold to achieve high cell densities. Such a system has been reported where Chinese hamster ovary (CHO) cells were photoencapsulated in PEG-DMA hydrogels using a modified SLA process (Dhariwala *et al.*, 2004). The technical issues associated with this fabrication technique are simply the union of those with standard SLA processes and photoencapsulation of living cells. Such challenges include attaining a reasonably small minimum feature size, producing tight resolutions, and maintaining high cell viability of encapsulated cells. In the process developed by Dhariwala *et al.*, minimum feature sizes of 150 microns in the *z*-direction and 250 microns in the *x-y* plane were achieved, which is similar to traditional SLA processes. As reported in previous photo-encapsulation studies, the cell viability was highly dependent on the concentration of photoinitiator used during processing.

### Direct Deposition of Cells

The concept of direct deposition of cells is another promising prospective approach to obtaining patterns of cells in arbitrary geometries. The direct deposition of cells using a spraying technique in combination with a patterning mask is a convenient method for creating two-dimensional patterning of cells. In this relatively straightforward method, a solution of cells is aerosolized using an off-the-shelf airbrush apparatus, creating a suspension of liquid droplets containing cells, which is directed toward a surface of collagen gel through a mask. Another collagen gel, approximately 400 microns in thickness, can be adsorbed to the surface, followed by additional repeated sequences of cell and collagen deposition. Increased cytochrome P450 activity, an assay for liver-specific cell function, was reported when patterning NIH 3T3 fibroblasts in conjunction with plated primary hepatocytes in a short-term culture. The ability to create arbitrary geometries of patterned cells in a collagen sandwich is an appealing technology to preserve polarity and function of hepatocytes cultured *in vitro* (Moghe *et al.*, 1996). This technique has been shown to produce features 120 microns in thickness from a mask with 100-micron features, and, though a collagen gel layer of 400 microns was used in the reported work, this thickness could be reduced significantly. The spraying process was shown not to dramatically affect cell viability or function of cultured human umbilical endothelial cells or primary hepatocytes. Although this approach is similar in principle to other techniques for cell patterning, including the use of micropatterned stamps or stencils (Folch *et al.*, 2000), the ability to combine patterned cell deposition with a layer-by-layer method can control the location of cells in the *z*-direction for newfound control. However, this approach requires the use of multiple masks for patterning cells in different geometries for each corresponding slice in the *x-y* plane.

Another method of direct cell deposition employs an off-the-shelf inkjet printer that uses a thermal ink deposition method, which is loaded with a suspension of CHO cells in a buffer solution (see Fig. 24.3f). Cells are then deposited in a precise manner onto hydrogel-based substrates, using a simple graphics program to define the location of the deposited cells in the  $x$ - $y$  plane. This process requires little modification to the commercially available printer, and, despite the extreme stresses on cells that are associated with the printing process, viabilities of approximately 90% were maintained in the deposition of the robust CHO cell line as a proof of concept. The resolution of inkjet printing of cell suspensions was shown to be on the order of hundreds of microns, which is typical of most previously described SFF methods. Although this approach has demonstrated only two-dimensional patterned deposition of one cell type, this technology represents a flexible platform for future development of three-dimensional cell-seeded scaffolds.

The noncontact manipulation of cells through the use of single-beam gradient optical traps is an efficient method of controlling the spatial coordinates of a variety of cell types in suspension. This technology, also termed *optical tweezers*, has been demonstrated in the manipulation of a variety of biological components, including cells, subcellular components, and microparticles coated with functional biomolecules. The use of high-numerical-aperture lenses leads to tight confinement of the micro- and nanoscale components along the beam axis, limiting the range of mobility in this direction, which ultimately leads to the drastic reduction in efficiency for depositing cells in this manner. By simply reducing the numerical aperture of the lens, micron- and submicron-sized particles can be directed along the beam path in a continuous stream and absorbed onto a target of interest. This general technique, termed *laser-guided direct writing*, has been applied to a variety of organic and inorganic particles as well as mammalian cells (Odde and Renn, 2000). During laser-guided deposition of cells, a laser emitting a near-infrared radiation is configured near a lens that is controlled using a three-axis micro-manipulator and directed into a chamber containing a suspension of embryonic chick spinal cord cells with a target substrate of untreated glass. As cells randomly drift into the path of the laser, a gradient force dominates and brings the cell to the center of the beam. The laser beam then directs the cell along the beam path until it reaches the substrate. The position of the single cells or streams of cells can be directed by manipulating the position of the lens. Cells have been deposited in multiple layers with resolutions of 1 micrometer, which offers a dramatic improvement over other methods of cell patterning. Furthermore, multiple sequences of cell deposition followed by the adsorption of a thin biomaterial layer could be cycled to create three-dimensional cell-seeded constructs. One potential

drawback to large-scale implementation of this technology could be the speed of deposition. In the reported system, cells were deposited onto the surface at a rate of 2.5 cells per minute. Although this rate could theoretically be raised by simply increasing the concentration of cells within the suspension, the patterned deposition of 100–1000 cells would take on the order of hours to complete.

## VI. SUMMARY AND FUTURE DIRECTION

Engineering the spatial and temporal microenvironments on a precise level is critical for inducing the desired cellular response, which is especially important in the field of tissue engineering and organ regeneration. Consequently, designing the microarchitecture of scaffolds used for said applications is an important first step in inducing favorable cell–matrix and cell–cell interactions. The need for micro-scale control has led to the development of a number of fabrication routes that are able to control the spatial location of scaffold features. One viable model that has produced the current state of the art and may continue to direct progress in the field of advanced scaffold manufacturing is the adaptation of traditional materials-processing techniques. Replica molding, electrodeposition, and solid free-form fabrication all represent examples of general materials-processing techniques that have been applied to develop advanced processing platforms for scaffold fabrication. This trend will likely continue as future technologies begin to mature, such as self-assembly and three-dimensional photolithography. The adaptation of nascent materials-processing technologies in the development of scaffold systems, where appropriate, could lead to advances in organ regeneration, with the potential for clinical therapy.

Often, the driving force for scaffold design and fabrication is the desire to create a biomimetic system. This manifests itself as designing materials and processes that try to mimic tissue properties such as microarchitecture, mechanical properties, surface topography, or chemical cues. The notion of the pursuit of biomimicry as effective design criteria for organ regeneration may or may not prove to be the most efficient means. However, for the time being, biomimetic strategies for scaffold fabrication provide challenges that drive the overall improvement of tissue engineering systems and technology. Advancing engineering systems at the present will therefore mature the technology in anticipation of the application of knowledge to be gained by future advancements in unraveling the complexity of biological systems, such as the further elucidation of the proteome and the mapping of cell signaling networks. Hence, the full potential of organ and tissue regeneration therapy in the future may only be realized on combining advanced scaffold fabrication techniques with design criteria outlined by information on fundamental biological processes derived from integrated systems biology.

### I. INTRODUCTION

Three-dimensional (3D) scaffolds serve as temporary substrates for supporting and guiding tissue formation in various *in vitro* and *in vivo* tissue-regeneration settings. Recent years have seen the emergence of scaffolds designed explicitly to control various aspects of the tissue-formation process. Spatiotemporal control of scaffold biochemical and physical properties has been investigated via incorporating fundamental molecular and cellular biomechanisms into scaffolds. Because living cells and tissues are highly complex systems, a central theme in designing tissue-engineering scaffolds is to understand how scaffold structures, properties, and functions are correlated. In this chapter, fundamental scaffold design variables (i.e., mass transport, mechanics, electrical conductivity, surface chemistry, and topology) are decoupled and analyzed in terms of how they have been engineered to control cell behavior through different constituent biomaterials and architectural structures. Approaches for temporal and spatial control are further described to illustrate principles that may guide integrated rational design of 3D scaffolds.

A key concept in tissue engineering (TE) is using material-based porous 3D scaffolds to provide physical support and a local environment for cells to enable and facilitate tissue development (Langer and Vacanti, 1993). Since the mid-1980s, 3D scaffolds have evolved to serve complex functions of guiding cellular behavior in different TE applications. Scaffolds can be seeded with embryonic or

adult stem cells, progenitor cells, mature differentiated cells, or cocultures of cells to induce tissue formation *in vitro* and *in vivo*; scaffolds can also be directly implanted *in vivo* with capabilities to deliver soluble/insoluble biomolecules and temporal/spatial cues to guide the function regeneration in defected tissues and organs. While the specific functions vary with tissue type and clinical need, scaffolds may potentially coordinate biological events at the molecular, cellular, and tissue levels on time and length scales ranging from seconds to weeks and nanometers to centimeters, respectively (Griffith, 2002). A central theme in designing tissue-engineering scaffolds is to understand the correlations between scaffold properties and biological functions.

During tissue development, cells constantly decode and release different morphogenetic factors in their surroundings. In response, cells make decisions on how to divide, differentiate, migrate, degrade/produce extracellular matrix (ECM), and orient themselves. Based on our understanding of cell-ECM interactions in native tissues, it should theoretically be possible to design scaffolds capabilities to promote tissue formation via logical, systematic variations in one or more chemical and/or physical properties. Living cells and tissues, however, are not simple, linear systems. The complex roles that ECM structures play in orchestrating cellular and tissue processes can be thought of as a multiband signal to which different cell types may exhibit radically different sensitivities. Moreover, the perfor-

mance of any scaffold property must be evaluated not only in the relatively controlled *in vitro* environment, but also in the context of the tissue's physiological function (e.g., under mechanical or electrical stimulation) and ultimately *in vivo*. The dynamic superposition of multiple scaffold properties with multiple environmental factors can profoundly impact the outcome of the tissue formation process. Correlations between individual scaffold properties and certain aspects of tissue formation (e.g., cellular phenotype and concomitant proliferation or ECM production) can be derived, and they have even been applied to the optimization of scaffold designs (Hollister, 2005). From an engineering standpoint, it is desirable that scaffold properties and their regulatory functions be reproducibly integrated within a scaffold design such that tissue formation can be induced and controlled in a stepwise manner *in vitro* and/or at the site of implantation *in vivo* (Lutolf and Hubbell, 2005; Stevens and George, 2005) (Fig. 25.1).

Owing to the innate complexity of biological systems, reproducing natural processes and engineering tissues with the aid of scaffolds presents a formidable task. Complications can arise on many fronts, such as from our incomplete understanding of native cell–ECM interactions, the difficulty of analyzing and standardizing biological systems, and even from our increasing technical capabilities to synthesize scaffolds, which may outstrip our understanding of how best to apply them. More questions can be raised, such as to what degree of complexity a tissue-engineering scaffold should be designed, how to coordinate different types of cellular and tissue events, and how scaffolds can be designed to function robustly in response to patient-specific variations and different clinical situations. In this chapter, we summarize current scaffold design approaches and essential principles that can guide the rational multifunctional design of scaffolds for tissue engineering. Design variables are decoupled and analyzed in terms of how they have been controlled using different materials and fabrication techniques and what implications they have in controlling the tissue formation process.

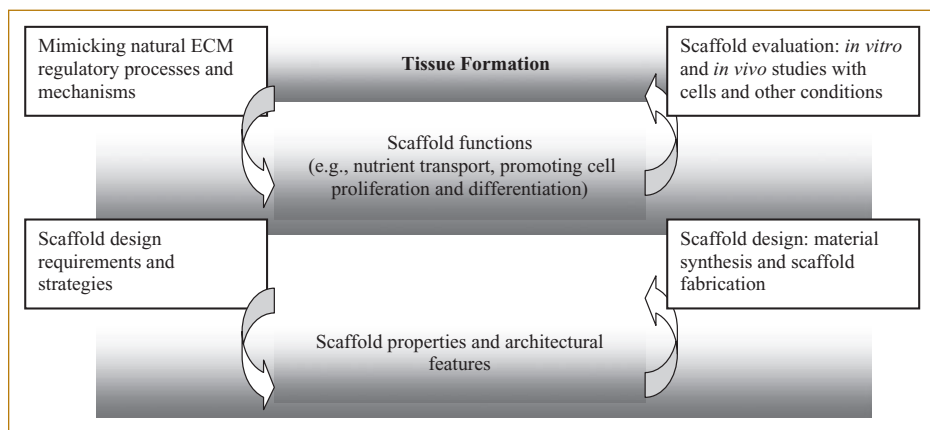

## II. THREE-DIMENSIONAL SCAFFOLD DESIGN AND ENGINEERING

From the perspective of material properties, mass transport, mechanics, electrical conductivity, surface chemistry, and topology all mediate cell behavior at the nano-, micro-, and macroscopic scales. These properties are often correlated with scaffold chemical compositions and structures in an interdependent way. For example, while a higher porosity may result in a beneficial increase in the mass transport capabilities of a scaffold, it may also compromise the scaffold's mechanical strength. Achieving optimal scaffold functional performance for a particular tissue-engineering application, therefore, requires balancing different factors.

An understanding of the fundamental scaffold properties and functions must form the foundation of any higher-order hierarchical scaffold design involving temporal and/or spatial controls. Temporally, the scaffold properties at the onset of *in vitro* seeding (i.e., time zero) or during the acute phase of the host response following direct implantation *in vivo* will provide an initial set of environmental conditions for cells and tissues. These initial scaffold properties and associated functions will then evolve over time in response to passive and active interactions with the culture environment and cells, respectively. Temporal features, enabled mainly by scaffold degradation and the release of bioactive factors, are obligatory for presenting time-appropriate signals corresponding with each particular stage of tissue development. Spatially, tissues and organs are 3D structures having a characteristic organization consisting of patterns of different types of cells and ECM constituents. Anisotropic biochemical and structural properties are designed in scaffolds to induce cell and ECM orientations and to guide multiscale organizations from molecular and cellular level up to the gross tissue or organ level.

### Mass Transport and Pore Architectures

The mass transport characteristics of a scaffold affect how fluid, solutes, and cells move in and out of a tissue con-

**FIG. 25.1.** Scaffold synthesis consists of processes to understand the design principles and develop enabling methodologies. On one hand, scaffold design is a deductive process entailing the proposition and testing of candidate scaffold properties and the cumulative elucidation of their independent and coupled reactions with cells and tissues. On the other hand, scaffold design is an inductive process, an exercise in recapitulating the wealth of tissue functions and cellular mechanisms observed throughout the body.

struct. As a porous 3D substrate, the mass transport in a scaffold at the initial stage is correlated with the scaffold's chemical compositions and the structural parameters of its pores or voids, characterized mainly by pore size, porosity, pore interconnectivity/tortuosity, and surface area. These scaffold characteristics interdependently affect the diffusive or convective behavior of soluble nutrients, growth factors, and cytokines. In addition to structural parameters, the local biochemical environment cellular activities can also influence the scaffold behavior (e.g., pH dependence of the hydrolysis of poly(lactic-co-glycolic acid) (PLGA) scaffolds). In scaffolds designed to deliver bioactive soluble factors, the release profile and distribution pattern of these factors will be influenced by the mass transport characteristics of the scaffold. Different from the vascularized tissues containing convective flows, diffusion is often the primary mass transport mechanism in engineered tissue constructs cultivated *in vitro* and prior to inosculation with the host vasculature following implantation *in vivo*. Theoretical models to simulate and predict the nutrient, protein, and cell diffusion processes in scaffolds have been developed (Botchwey *et al.*, 2003; Malda *et al.*, 2004).

Once a scaffold is impregnated with cells, the solute diffusion and distribution profiles are influenced mainly by the cell organization. In metabolically active tissues *in vivo*, most cells reside within 100  $\mu\text{m}$  of a capillary. In engineered tissue constructs cultivated in static culture without medium perfusion, neotissue formation is generally limited to the peripheral 100–200  $\mu\text{m}$  of the scaffold, due to diffusion limitations (Colton, 1995; Ishaug *et al.*, 1997; Freed *et al.*, 1998). Subsequently, the organization and density of cells in this peripheral region can further influence the distribution and availability of nutrients to cells within the scaffold interior (Malda *et al.*, 2004). Although certain types of cells may tolerate nutrient deficiency to some extent (such as chondrocytes under hypoxia), the induction of rapid vascularization following implantation is considered essential to establishing nutrient exchange and to the retention of a viable cell population within an engineered tissue construct. The structural characteristics of the pores and void spaces in scaffolds are the primary variables governing the initial cell distribution and organization in scaffolds.

One main parameter that affects the efficiency of initial cell impregnation is the pore size of the scaffold. The resulting geometries and spatial characteristics of individual cells or cell aggregates within the void space of scaffolds direct the subsequent cell proliferation, differentiation, and tissue formation events. As observed in nonwoven fibrous scaffolds made of poly(ethylene terephthalate) (PET) and seeded with human placenta trophoblast cells *in vitro*, the size of cell aggregates increased with larger pore volumes between fibers (T. Ma *et al.*, 1999). Variations in cell behavior were also observed, with attenuated differentiation and suppressed proliferation activities in larger cell aggregates compared to smaller ones (T. Ma *et al.*, 1999, 2000). Optimal

scaffold pore sizes have been suggested for regenerating various types of tissues *in vivo*. The critical pore size was found to be above 500  $\mu\text{m}$  for rapid fibrovascularization in poly(L-lactic acid) (PLLA) scaffolds with cylindrical pores (Wake *et al.*, 1994). In ECM analog scaffolds (made of cross-linked collagen and glycosaminoglycans [GAGs]), the average pore diameters required to induce dermis and peripheral nerve regeneration were within 20–120  $\mu\text{m}$  and 5–10  $\mu\text{m}$ , respectively (Yannas, 2005). In bone engineering, early studies by Hulbert *et al.* (1970) showed that a minimum pore size of 100  $\mu\text{m}$  was required to allow bone tissue ingrowth in ceramic scaffolds. Further investigations were carried out to understand the pore size requirement for bone tissue engineering. Although the optimal pore size varied with scaffold material and other parameters, such as tortuosity, the general consensus is that larger pore sizes (e.g., >100  $\mu\text{m}$ ) may favor higher alkaline phosphatase activity and more bone formation (Tsuruga *et al.*, 1997; Karageorgiou and Kaplan, 2005).

Cell transport and vascularization as a result of scaffold pore size can also affect the tissue types and tissue formation process in scaffolds. When bone morphogenetic proteins were loaded into honeycomb-shaped hydroxyapatite scaffolds to induce osteogenesis, it was found that smaller diameters (90–120  $\mu\text{m}$ ) induced cartilage formation followed by bone formation, whereas those with larger diameters (350  $\mu\text{m}$ ) induced bone formation directly (Kuboki *et al.*, 2001). The difference was likely caused by the different onset time of vascularization and cell differentiation.

In addition to pore size, cell transport within a scaffold such as diffusion, attachment, and migration are controlled by porosity (the fraction of pore volume), pore interconnectivity, and available surface area in scaffolds. While a high porosity is often desired, it is inversely related to the surface area available for cell attachment in 3D scaffolds. Achieving an optimal cell density in scaffolds therefore necessitates a high surface-area-to-volume ratio. In order to facilitate the transport of cells and bioactive chemicals, scaffolds may also need to have pores at both macro and micro scales, features that may be difficult to obtain via traditional scaffold fabrication techniques, such as particle leaching, gas foaming, and phase separation. Rapid-prototyping techniques such as solid free-form fabrication (SFF) are emerging as important methods to generate highly controlled scaffold structures. Compared to scaffolds fabricated with traditional methods, the pore size and tortuosity in rapid-prototyped scaffolds have much narrower variations in structural distribution. Local topologies can also potentially be optimized by computational algorithms to control the permeability and mechanical properties (Hollister, 2005). Studies have been carried out to compare scaffolds fabricated by controlled processes with those containing irregular structures fabricated by conventional methods. In one such study, scaffolds with similar porosities were prepared by particle leaching or by 3D fiber deposition and compared

**FIG. 25.2.** Designer scaffolds offer opportunities to control scaffold properties such as pore structures, surface area, and mechanical strength. Electron micrographs of scaffolds fabricated by the conventional methods of compression molding and particle leaching (A) and 3D fiber deposition (B). for their ability to support cartilage tissue growth (Malda *et al.*, 2005) (Fig. 25.2). A significantly higher glycosaminoglycan (GAG) content was observed in the scaffolds fabricated by the controlled 3D fiber deposition process. Besides the fibrous morphology and highly accessible pores, more uniform and efficacious cell diffusion/attachment may also have contributed to the observed up-regulation of GAG production and the better scaffold function. Advanced scaffolds fabricated by tightly controlled methods, with more uniform and controllable structures and properties, therefore hold promise in promoting the reproducible formation of functional engineered tissues.

## Mechanics

The mechanical properties of the natural ECM are of paramount importance in dictating macroscopic tissue functions (e.g., bearing load) and regulating cellular behavior via mechanotransduction signaling. In designing tissue constructs, scaffold mechanical properties are often sought that resemble native tissue properties. Foremost, in the acute phase following implantation the scaffold must fulfill the key mechanical functions of the tissue being replaced. For example, the earliest TE blood vessels based on cell-contracted collagen gels were not strong enough to withstand physiologic blood pressures, and thus they had to be reinforced by a tubular synthetic polymer mesh to ensure structural integrity (Weinberg and Bell, 1986). More recent

TE blood vessels based on relatively strong nonwoven poly(glycolic acid) (PGA) scaffolds exhibited burst pressures exceeding physiological requirements upon implantation ( $>2000$  mmHg) (Niklason *et al.*, 1999). In addition to appropriately matching gross tissue mechanical properties, the scaffold must also provide an internal micromechanical environment conducive of the *de novo* synthesis and organization of ECM. For example, while nonwoven PGA scaffolds have been successfully employed in blood vessel (Niklason *et al.*, 1999) and heart valve TE (Sutherland *et al.*, 2005), their application to myocardial tissue has been comparatively challenging (Papadaki *et al.*, 2001). In contrast to the predominant load-bearing functions of vessels and valves, the primary function of myocardial tissue is cyclic contraction. While the out-of-plane compressive modulus of a typical nonwoven PGA scaffold is relatively low ( $\sim 6.7 \pm 0.5$  kPa) (Kim and Mooney, 1998), the in-plane tensile and compressive moduli resisting cardiomyocyte-mediated contraction are comparable, at  $\sim 284 \pm 34$  kPa (Engelmayr and Sacks, 2006). To understand the role of material elasticity on cell behavior, myoblasts were cultured on collagen strips attached to glass or polymer gels of varied elasticity (Engler *et al.*, 2004). Cells were found to differentiate into a striated, contractile phenotype only on substrates within a very narrow range of musclelike stiffnesses (i.e., 8–11 kPa) (Fig. 25.3). To optimize a scaffold design for a particular application requires consideration of the gross organ and tissue-level functional requirements as well as the micro-mechanical requirements for appropriate tissue formation at the cellular level.

The mechanical properties of TE scaffolds are determined in part by the bulk properties of their constituent materials (e.g., modulus of elasticity, degradation rate). For example, most hydrogel materials exhibit a much lower strength and stiffness than hydrophobic polyester materials. Because traditional PLGA-based scaffolds have a limited subset of mechanical properties, new biodegradable materials have been developed, such as poly(hydroxyalkanoates) and poly(glycerol sebacates), to improve scaffold toughness and elasticity (Zinn *et al.*, 2001; Wang *et al.*, 2003). Because of the high porosity and concomitant low material content, the mechanical properties of TE scaffolds are very often dictated primarily by the structural arrangement of their constituent materials (e.g., pore size, fiber diameter, and orientation; Table 25.1) and associated modes of structural degeneration (e.g., fiber fragmentation, bond disruption). For example, in a recent study the effective stiffness (*E*) (equivalent to initial tensile modulus) of nonwoven PGA scaffolds was predictably modulated by tuning the fiber diameter via NaOH-mediated hydrolysis (Engelmayr and Sacks, in press).

In addition to the initial structure imparted during the fabrication of the TE scaffold, the modes of structural degeneration manifested by the scaffold need to be considered. For example, while 50 : 50 blend PGA/PLLA scaffolds do

**FIG. 25.3.** To understand the role of material elasticity on cell behavior, myoblasts were cultured on collagen strips attached to glass or poly(acrylamide) gels of varied elasticity. Substrate stiffness was found to have a profound influence on myocyte differentiation, with optimal differentiation (as assessed by striation) occurring within a very narrow range of musclelike stiffnesses (i.e., 8–11 kPa) (Engler *et al.*, 2004). These results suggest that cell differentiation within 3D tissue-engineering scaffolds may exhibit a similar sensitivity to the local micromechanical properties. Figure reproduced with permission of the Rockefeller University Press.

not undergo significant mechanical degeneration over a period of three weeks (Engelmayr *et al.*, 2005), scaffolds dip-coated with the biologically derived thermoplastic poly(4-hydroxybutyrate) (P4HB) incur a rapid loss of rigidity with cyclic flexural mechanical loading as the P4HB bonds between fibers are disrupted (Engelmayr *et al.*, 2003). Depending on the kinetics of scaffold hydrolysis, structural degeneration may be more pronounced and thus such kinetics represent a more important consideration in scaffold design.

Because the foremost role of the scaffold following implantation is temporarily to fulfill the key mechanical functions of the replaced tissue, it is essential to consider the physiological loading state of the native tissue. While the physiological loading state may be highly complex and virtually impossible to reproduce *ex vivo*, certain mechanical testing configurations are generally more relevant than others. For example, the physiological loading state of a semilunar heart valve leaflet depends on time-varying solid–fluid coupling (i.e., leaflet tissue–blood) and includes multiaxial flexural, tensile, and fluid shear stress components. In light of the strong planar anisotropy and trilayered structures exhibited by native leaflet tissues, biaxial tensile testing (Grashow *et al.*, 2006) and flexural testing (Mirnajafi *et al.*, 2005) have been employed to characterize their behavior.

Because engineered tissues based on synthetic polymer scaffolds inherently begin development as composite materials, their effective mechanical properties will be determined by the combined effects of the cells, ECM, and scaffold and their unique micromechanical interactions. Thus, the appropriate formulation and validation of a mathematical model to simulate and/or predict the mechanical properties of a scaffold are critical prerequisites for developing a mathematical model to simulate and/or predict the

**Table 25.1.** Dependence of a scaffold mechanical property (initial tensile modulus) on the bulk material mechanical property and scaffold structure<sup>a</sup>

Material	Initial tensile modulus (MPa)		
	Fibrous scaffold	Foam scaffold	Bulk material
Poly(glycolic acid) (PGA)	0.284 ± 0.034 (nonwoven) (Engelmayr and Sacks, in press)	0.919 ± 0.067 <sup>b</sup> (salt leach) (Beatty <i>et al.</i> , 2002)	18,780 ± 3430 (fiber) (Engelmayr and Sacks, in press)
Poly(ester urethane)urea (PEUU)	8 ± 2 (electrospun) (Stankus <i>et al.</i> , 2004)	~1.4 <sup>c</sup> (TIPS <sup>d</sup> ) (Guan <i>et al.</i> , 2005)	60 ± 10 (film) (Stankus <i>et al.</i> , 2004)
Poly(glycerol sebacate) (PGS)	N/A	0.004052 ± 0.0013 (salt leach) (Gao <i>et al.</i> , in press)	0.282 ± 0.0250 (film) (Wang <i>et al.</i> , 2002)

<sup>a</sup>Several order-of-magnitude differences in modulus can be realized by starting with different bulk materials and/or by converting the bulk material into different porous scaffold structures (e.g., foam or fibrous). For comparison, the initial tensile modulus of a typical passive muscle tissue was reported to be 0.012 ± 0.004 MPa (Engler *et al.*, 2004).

<sup>b</sup>Aggregate modulus obtained from creep indentation testing of PGA-PLLA scaffold.

<sup>d</sup>Thermally induced phase separation.

mechanical properties of an engineered tissue. While standard phenomenological models may be useful in characterizing the gross mechanical behavior of a scaffold or engineered tissue construct (i.e., for meeting organ- and tissue-level functional requirements), only an appropriately formulated structural-based model can be used to design the micromechanical environment presented at the cellular level. Structural-based models can be either computationally driven, as in the work of Hollister *et al.* (Hollister *et al.*, 2002; Hollister, 2005) or purely analytical, as in the case of a model for nonwoven scaffolds by Engelmayr and Sacks (in press). Irrespective of the solution method, the goals of structure-based modeling are both to bridge the gap between the disparate length scales of cells, tissues, and scaffolds and, in particular, to simulate accurately the micromechanical environment presented at the cellular level. For example, while traditional rule-of-mixtures theories accounting for the volume fractions and orientations of individual composite constituents are often invoked in describing native and engineered tissues (Gibson, 1994), higher-order reinforcement effects observed via the structural-based modeling of commercially available nonwoven PGA and PLLA scaffolds preclude the use of rule-of-mixtures approaches. These higher-order reinforcement effects, which yield proportional increases in fiber effective stiffness with increased ECM stiffness, predict a very different micromechanical environment than that predicted by a rule of mixtures, highlighting the importance of an accurate micromechanical representation of the TE scaffold.

### Electrical Conductivity

Electrical conduction is an important mechanism that enables cellular signaling and function in many types of tissues. The cardiac electrical conduction system is essential to maintaining synchronous beats that pump blood in an ordered fashion. In the process of bone regeneration, naturally occurring piezoelectric properties of the apatite crystal are hypothesized to generate electric fields involved in bone remodeling. The nervous system possesses the well-known system of electrochemical signaling. Much research has been carried out using materials to record from and influence bioelectric fields. In making tissue scaffolds, electrically conductive biomaterials have been studied to understand their abilities to interface with bioelectrical fields in cells and tissues to replicate normal electrophysiology.

A wide variety of electrically conductive polymers is available to the tissue engineer, each with differing characteristics that may direct the choice for a given application. These organic compounds include poly(pyrrole), poly(vinylidene fluoride), poly(tetrafluoroethylene), poly(aniline), poly(thiophene), and poly(acetylene). Such polymers generally contain delocalized pi bonds and can be considered semiconductors, with conductivity determined by degree of doping. Polypyrrole, an aromatic heterocycle, is perhaps the most widely studied conductive biomaterial,

due to both ease of fabrication and demonstrated biocompatibility. In contrast to static charge seen in conductive materials like poly(pyrrole), piezoelectric materials such as poly(vinylidene fluoride) display transient charge in response to mechanical deformation. For transplantation purposes, it is often desirable to have the material biodegrade after cell delivery and incorporation into the host environment have been accomplished. Degradable conductive polymers have been synthesized using several different approaches, including incorporation of three-substituted hydrolyzable side groups (Zelikin *et al.*, 2002), degradable ester linkages connecting oligomers of pyrrole and thiophene (Rivers *et al.*, 2002), and emulsion/precipitation of poly(pyrrole) in poly(D,L-lactide) (Shi *et al.*, 2004).

In order to tailor conductive biomaterials to a given application, scalable technologies have been developed to fabricate conductive structures of arbitrary geometry. Due to horizontal and vertical growth of poly(pyrrole) during electropolymerization, two-dimensional photolithographically defined gold layers can be used to pattern three-dimensional structures (LaVan *et al.*, 2003; George *et al.*, 2005). Hollow polymer tubes ranging from the nano to the micro scale have been fabricated using a range of techniques, including polymerization via electrodes on opposite ends of a silicone tube (Chen *et al.*, 2000) or via oxidation on platinum wire molds followed by reduction (Saigal *et al.*, 2005).

A growing number of reports are demonstrating synergistic effects of conductive biomaterials and electrical stimulation. Neonatal cardiomyocytes cultured on collagen sponges and matrigel show synchronized contraction in response to applied electric fields (Radisic *et al.*, 2004; Gerecht-Nir *et al.*, 2006). Applied potentials can also be used to change surface properties of conductive polymers, altering cell shape and function, including DNA synthesis and extension (Wong *et al.*, 1994). Others have shown that electrical stimulation promotes neurite outgrowth on conductive polymers beyond that seen on indium-tin oxide, an inorganic conductive substrate (Schmidt *et al.*, 1997). Composite conductive polymer films have been manufactured to include substrates that direct cell function, such as hyaluronic acid to promote angiogenesis (Collier *et al.*, 2000).

The mechanistic basis for each of these electrical-material-tissue interactions is not fully understood and will be an important area for future study. However, some leading hypotheses have emerged. This enhanced function of engineered cardiac tissues may be due to greater ultrastructural organization in response to electric fields (Radisic *et al.*, 2004). Increased neurite outgrowth with electrical stimulation may be caused by better ECM protein adsorption (Kotwal and Schmidt, 2001) rather than direct effects on the cell itself, although there is ample evidence of the latter. Electrophoretic redistribution of cell surface receptors likely governs the galvanotropic response of neurons to a horizontally oriented two-dimensional applied field

(Patel and Poo, 1982). Such mechanisms do not fully explain altered cell function in response to stimulation applied to the substrate or material relative to the medium or a distant ground. For such depolarization, signaling through voltage-gated calcium channels can activate ubiquitous second messengers such as cAMP and alter gene transcription, affecting learning, memory, survival, and growth (West *et al.*, 2001). Such secreted gene products might be used to enhance the survival of host cells surrounding an implanted scaffold. Given that applied electric fields can so profoundly affect cell function, conductive three-dimensional scaffolds will be important tools for harnessing this interaction to create functional tissues.

### Surface Properties

Cells interact with scaffolds primarily through the material surface, which can be dominated by the surface chemical and topological features. The surface chemistry here refers to the insoluble chemical environment that the scaffold surface presents to cells. Such environment is dictated by the biochemical compositions of the bulk and/or the substances resulting from the surface adsorption or chemical reactions. Besides mediating cell behavior and functions inside scaffolds, controlled surface properties are of central importance in directing the inflammatory and immunological responses. Controlled surface properties may be useful for ameliorating the foreign-body reaction at the host–scaffold interface *in vivo* (Mikos *et al.*, 1998; Hu *et al.*, 2001).

### Surface Chemistry

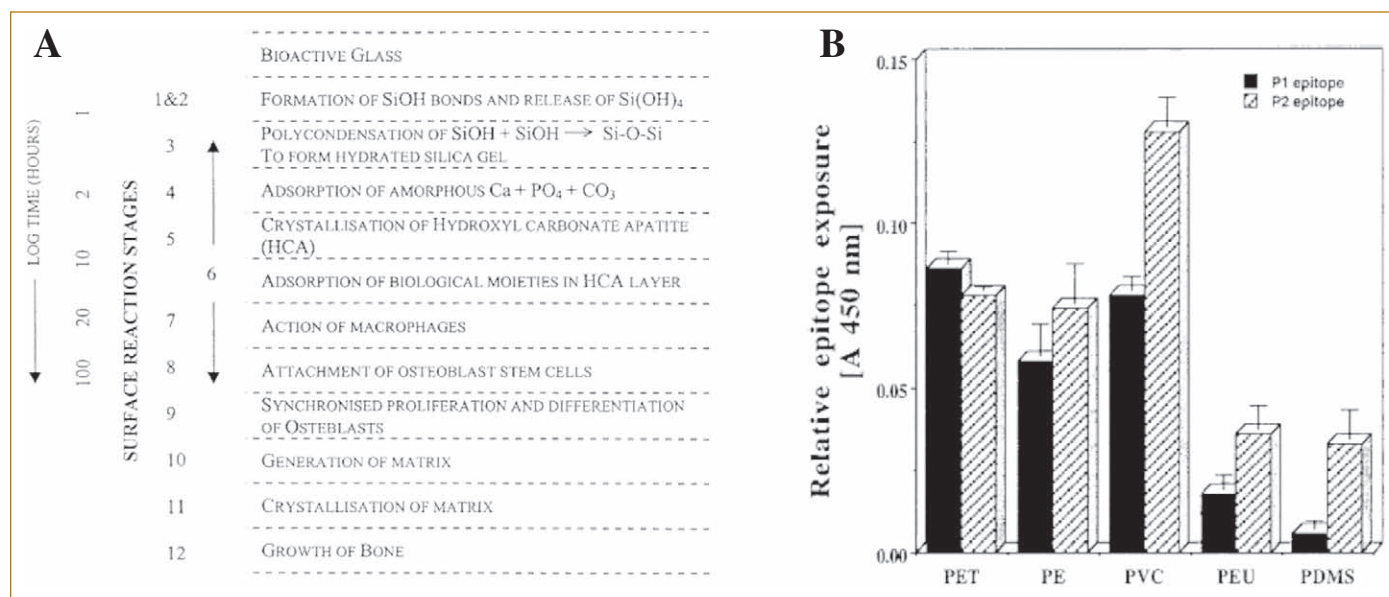

Each type of synthetic, natural, or composite scaffold gives rise to a set of distinct surface chemical characteristics governed by the material chemistry and its physical form (such as crystallinity, charge, and topology). Although numerous efforts have been made to tailor the scaffold surface, the chemical environment can exhibit extremely complicated patterns within the biological milieu. Complex processes, such as the spontaneous adsorption of a diversity of proteins from biological fluids to the scaffold surface and the protein surface conformation, are difficult to analyze, though they exert profound effects on the scaffold performance. To tailor the scaffold chemical properties, the interactions of scaffolds with different environmental factors need to be considered.

Scaffolds derived from natural ECM materials, such as collagen, fibrin, hyaluronic acid (HA), proteoglycans, or their composites, have the advantages of directly containing innate biological ligands that cells can recognize and provide natural mechanisms for tissue remodeling. ECM analogs have been created to emulate an appropriate tissue-regeneration environment. For example, as an essential ECM component in natural cartilage tissue, collagen type II scaffolds may have better biochemical properties to maintain chondrocyte phenotype and enhance the biosynthesis of glycosaminoglycans compared to collagen type I (Nehrer

*et al.*, 1997). Fibrin, the native provisional matrix of blood clots, can provide ligands to initiate cell attachment and ECM remodeling (Hubbell, 2003). HA plays a role in morphogenesis, inflammation, and wound repair, and the cell–ECM interactions mediated through receptors such as CD44 and RHAMM can be activated in scaffolds with HA constituents (Hubbell, 2003). The natural cell–ECM interactions, however, can also alter after purification, manufacturing, and scaffold fabrication processes. For example, acid-treated type I collagen polymers contained only 5% residual crystallinity as compared to native collagen. The loss of crystalline structure led to platelets binding with diminished degranulation, which in turn limited the myofibroblast numbers and the related inflammatory response at the injured site (Yannas, 2005).

Synthetic scaffolds offer a variety of mechanisms to modulate cell behavior. Chemical reactions with biological fluid remodel the scaffold surface and affect tissue growth through both reaction dynamics and kinetics. Studies have shown that bioactive glasses (Class A bioglass composed of 45–52% SiO<sub>2</sub>, 20–24% CaO, 20–24% Na<sub>2</sub>O, and 6% P<sub>2</sub>O<sub>5</sub>) have osteopductive properties superior to those of either bioactive hydroxyapatite or bioinert metals and plastics. The difference was found due to the surface reaction kinetics in physiological fluid. The rapid reaction rate that converts amorphous silicate to polycrystalline hydroxyl-carbonate apatite on the bioglass surface is the key to positively regulating the cell cycle and bone formation (Hench *et al.*, 2000) (Fig. 25.4A). Physical processes also play active roles in controlling the material–cell interface. Because of the adsorbed protein moieties from serum or body fluid, many polyester-based scaffolds, such as those made from poly( $\alpha$ -hydroxy esters), exhibit adequate adhesion to support cell attachment and tissue growth in some *in vitro* and *in vivo* applications. Methods that alter the surface hydrophobicity, e.g., by changing monomer compositions or by chemical surface treatment, can potentially improve the scaffold performance (Mikos *et al.*, 1994; Gao *et al.*, 1998; Harrison *et al.*, 2004). For example, biodegradable foams of hydrophobic polymers (e.g., PLLA and PLGA) can be efficiently wet by two-step immersion in ethanol and water. This surface treatment could overcome the hindered entry of water into air-filled pores to facilitate cell seeding (Mikos *et al.*, 1994).

Surface modifications of scaffolds have been developed to generate surface chemical specificity and recognition. The surface chemistry can be created by either incorporating bioactive moieties directly in the scaffold bulk or modifying the surface. These moieties bound to scaffolds trigger desired specific intracellular signaling. In particular, many synthetic and natural hydrogel materials (e.g., poly[ethylene glycol], poly[vinyl alcohol], alginate, and dextran) are protein repellent, and immobilizing biomolecules to such hydrogel scaffolds may be especially useful in tailoring the surface chemistry for cell–material interactions at the molecular level.

**FIG. 25.4.** Understanding the molecular basis of surface interactions is essential to controlling surface functions. **(A)** A series of surface reactions on Class A bioglass (Hench *et al.*, 2004). Figure reproduced with permission from Springer. **(B)** Dynamic and kinetic mechanisms of material interactions with proteins can lead to different cell response at the scaffold surface. The example shows the exposure of two epitopes (P1 and P2) in fibrinogen on a surface varied with the substrate materials (PET, PE, PVC, PEU, and PDMS disks coated with human fibrinogen) (Hu *et al.*, 2001). Figure reproduced with permission from the American Society of Hematology.

Cell adhesion mediated through extracellular adhesive proteins is involved in many intracellular signaling pathways that regulate most fundamental cell behaviors, including differentiation, proliferation, and migration. Enriching scaffold surfaces with specific ECM-derived adhesion proteins has been widely applied to scaffold modification. PLGA-based scaffolds have been coated with fibronectin by physical adsorption for supporting growth and differentiation of human embryonic stem cells in 3D (Levenberg *et al.*, 2003). Fibronectin was covalently attached to PVA hydrogels for improved cell adhesion, proliferation, and migration (Nuttelman *et al.*, 2001). Fibrinogen was also denatured and fused into the backbone of a PEG hydrogel material (Seliktar, 2005) to elicit cellular responses. Elucidating the underlying molecular mechanisms on scaffold surface, however, is not a trivial task. Fundamental studies have been carried out to understand how the adsorption and denaturing of proteins can lead to different cellular responses at the material surface and may provide a molecular basis to control cell–material interaction and specificity for rational scaffold design (Hu *et al.*, 2001) (Fig. 25.4B).

Immobilizing peptide ligands derived from the active domains of ECM adhesion proteins to scaffolds is another major approach to generate specific surface-bound biological signals. For example, integrins, the principal adhesion receptor mediating cell–ECM attachment, comprise a family of more than 20 subtypes of heterodimeric transmembrane proteins. Each of them recognizes and interacts with certain

types of ECM adhesion proteins to activate a cascade of signaling pathways to regulate essential cell activities and functions (Plow *et al.*, 2000). Integrins can be activated by short peptides in similar ways, e.g., Arg-Gly-Asp (RGD) from fibronectin and Tyr-Ile-Gly-Ser-Arg (YIGSR) from laminin. Provided that peptides are relatively stable and economical to use, incorporating them into scaffolds has become an important way to generate surface biomimicry and enhance tissue regeneration (Hersel *et al.*, 2003; H. Shin *et al.*, 2003). To introduce peptide moieties, the scaffold materials need to contain appropriate functional groups, which may not be available in most hydrophobic polyesters. Methods have been developed to functionalize polyesters. For example, poly(lactic acid-co-lysine) has been synthesized, and the RGD peptide can be immobilized through the side-chain amine groups of the lysine residues (Barrera *et al.*, 1993; Cook *et al.*, 1997).

Like the biomolecules in natural ECM, the functions of immobilized bioactive ligands in modulating membrane receptors and intracellular signaling are influenced by their spatial characteristics. For example, integrin affinity to ECM affects cell attachment and migration. As a result, 3D neurite migration demonstrated a biphasic dependence on RGD concentration, with intermediate adhesion site densities (between 0.2 and 1.7 mol of peptide/mol of fibrinogen) yielding maximal neurite extension as compared with higher densities, which inhibited outgrowth (Schense and Hubbell, 2000). In another study, integrin clustering, a prerequisite to many integrin-mediated signaling pathways, was reca-

pitulated by RGD nanoclusters immobilized on a comb-polymer substrate (Maheshwari *et al.*, 2000).

### Surface Topography

The material–cell interactions mediated through topographical features have traditionally been studied through planar substrates. Surface modification techniques, including photolithography, contact printing, and chemical treatments, have been developed to generate micro- and nano-scale surface topographical features. Surface topographical features such as ridges, steps, and grooves were found to guide cytoskeletal assembly and cell orientation. Surfaces with textures such as nodes, pores, or random patterns are often associated with marked changes of cell morphology, cell activities, and the production of autocrine/paracrine regulatory factors as compared to smooth surfaces (Flemming *et al.*, 1999). In general, surface roughness increases cell adhesion, migration, and the production of ECM. Cells sense and respond to topographical features in a dimension-dependent way. As demonstrated on titanium surfaces, whereas microtextures increased osteoblast attachment and growth, only the presence of nanoscale roughness led to enhanced cell differentiation in connection with elevated growth-factor production (Zinger *et al.*, 2005).

Current fabrication techniques can be used to generate a wide variety of topographical features in scaffolds. Scaffolds can be randomly packed with regular or irregular geometries and shapes (e.g., particles, pellets, and fibers) or condensed with amorphous structures (e.g., foam and sponge) or fabricated with specifically designed architectures. Based on the cell–material interactions, scaffolds provide different topographical properties correlated with the dimensions of scaffold geometries and shapes. When the feature size is larger than or comparable to that of cells, e.g., the fiber diameter in a nonwoven mesh and pores and walls in a foam, the scaffold may provide curved surfaces for cell attachment. Pore size and surface area constitute the major topological features in an extracellular environment. As demonstrated in a study of mesenchymal stem cells seeded onto polymeric fibrous fabrics, increased fiber diameter favored cell attachment and proliferation by providing more surface area (Takahashi and Tabata, 2004). Surface treatment techniques such as sodium hydroxide etching have been used to generate nanoscale roughness to increase cell adhesion, growth, and ECM production (Pattison *et al.*, 2005).

The size scale of most natural ECM components, e.g., fibrous elastin and collagen, fall into the range of several to tens of nanometers. The extracellular environment is dominated by nanoscale topographical features, such as nanopores, ridges, fibers, ligand clusters, and high surface-area-to-volume ratios in 3D. Such native topographies can be recapitulated to a degree in scaffolds made of natural ECM polymers, such as collagen and elastin. Because syn-

thetic materials have the advantage of greater control over scaffold properties, interest is growing in developing synthetic nanofibrous scaffolds. Three-dimensional PLLA-based scaffolds containing nanofibers have been produced by thermally induced phase separation processes (Woo *et al.*, 2003; F. Yang *et al.*, 2004), and selective surface adsorption of adhesion proteins was observed. In a more versatile method, electrospinning techniques have been used to fabricate a variety of synthetic and natural materials with different hydrophobicities into fibers with diameters ranging from a few to hundreds of nanometers (Z. Ma *et al.*, 2005). Another important approach involves building scaffolds from the bottom up. Polypeptides made of 12–16 amino acids have been designed to form hydrogel scaffolds through  $\beta$ -sheet assembling (Zhang, 2002). Amphiphilic molecules consisting of a hydrophilic peptide head and a hydrophobic alkyl tail self-assemble into nanocylinders to form interwoven scaffolds (Hartgerink *et al.*, 2002; Silva *et al.*, 2004).

Nanofibrous scaffolds have demonstrated abilities to support cell and tissue growth. For example, when cardiomyocytes were cultured in meshes made of electrospun poly( $\epsilon$ -caprolactone) nanofibers, they expressed cardiac-specific markers and were contractile in 3D scaffolds (M. Shin *et al.*, 2004). In a scaffold based on self-assembled peptide amphiphilic molecules containing the laminin epitope IKVAV, neural progenitor cells selectively differentiated into neurons (Silva *et al.*, 2004). The potential of designing nanoscale topographies in scaffolds remains largely unknown with regard to exactly how cell cycle, gene expression patterns, and other cell activities are regulated. Some possible mechanisms may be related to cell receptor regulation (clustering, density, and ligand-binding affinity) on nanofibers, nutrient gradients in nanoporous matrices, mechanotransduction induced by the unique matrix mechanics, and the conformation of adhered proteins for cellular recognition sites.

## Temporal Control

### Scaffold Degradation

Unlike permanent or slowly degrading implants, which may serve to augment or replace organ function (e.g., hip implants, artificial hearts, or craniofacial plates), tissue-engineering scaffolds serve as temporary devices to facilitate the tissue healing and regeneration process. The regeneration of a fully functional tissue ideally coincides in time with complete scaffold degradation and resorption. Controlling degradation mechanisms allows scaffolds to cooperate temporally with cell and tissue events via changes in scaffold properties and functions. Tuning the scaffold degradation rate to make it kinetically match with the evolving environment during tissue healing and regeneration is an important design criterion. Due to the multiple roles of scaffolds, the interrelations between scaffold property variables, and the different wound conditions in individual

patients, it remains a challenge to design degradation properties that can be tailored to meet various clinical tissue regeneration requirements.

During scaffold degradation, some scaffold properties and functions may weaken or diminish with time. In general, there exist lower and upper limits on the optimal degradation rate, which may vary with different cellular or tissue processes, scaffold chemical compositions, and scaffold functions. For example, scaffolds often need to serve mechanical functions, such as in bone implants to support compressive loading while maintaining an environment permissive to new bone formation. If a material degrades prior to transferring mechanical load to the new tissue, the therapy would fail (K. Y. Lee *et al.*, 2001). Alternatively, materials in bone implants that degrade too slowly may cause stress shielding, thereby impeding the regeneration process and potentially endangering surrounding tissues (Cristofolini, 1997). In skin wound models, healing can be compromised when the scaffold degradation occurs too quickly, whereas scar tissue occurs when the degradation is too slow (Yannas, 2005). The optimal skin synthesis and prevention of scar formation could be achieved when the template was replaced by new tissue in a synchronous way; i.e., the time constant for scaffold degradation ( $t_d$ ) and the time constant for new tissue synthesis during wound healing ( $t_h$ ) were approximately equal (Yannas, 2005). Matching tissue formation with material degradation thus requires coupling of specific temporal aspects of tissue formation processes with chemical properties of the scaffold.

Scaffold degradation can occur through mechanisms that involve physical or chemical processes and/or biological processes that are mediated by biological agents, such as enzymes in tissue remodeling. Degradation results in scaffold dismantling and material dissolution/resorption through the scaffold bulk and/or surface. In the passive degradation mode, the degradation is often triggered by reactions that cleave the polymer backbone or cross-links within the polymer network. Many polyester scaffolds made of lactic acid and glycolic acid, e.g., PLLA and PLGA, undergo bulk backbone degradation due to their wettability and water penetration through the surface. Hydrophilic scaffolds such as hydrogels made of natural or synthetic materials cross-linked by hydrolyzable bonds (e.g., ester, carbonate, or hydrazone bonds) also convert to soluble degradation products, predominantly through the bulk (K. Y. Lee *et al.*, 2000; Ferreira *et al.*, 2005). Chemical degradation can be conveniently varied through scaffold physical and chemical properties, such as the backbone hydrophobicity, crystallinity, glass transition temperature, and cross-link density. Because of this flexibility, the degradation rate can be engineered principally for optimal tissue regeneration (K. Y. Lee *et al.*, 2001; Tognana *et al.*, 2005).

Scaffolds degrading through passive mechanisms exhibit limited capabilities to match with tissue growth and

wound healing. In bulk degradation, the accumulation of degradation products may exert adverse effects on tissue, e.g., acidic products from PLGA degradation. It is also difficult to tailor the degradation to match the healing rate, which may vary with wound conditions, such as age of the patient, severity of the defect, and presence of other diseases. In order to exert more control over the degradation properties of a scaffold and to attempt to tailor the degradation of the scaffolds, consideration of pertinent wound-healing and tissue-regeneration mechanisms is required. For example, wound healing is a highly complex yet orchestrated cascade of events, controlled by a vast array of cytokines and growth factors, that generally involves three phases, including inflammation, granulation tissue formation, and remodeling of the ECM. Scaffolds should be designed to degrade *in vivo* during the formation of granulation tissue and/or during the remodeling process. Ideally these materials should withstand uncontrolled dissolution or degradation at physiologic conditions while being resorbed by natural cell-mediated processes. Many inorganic scaffolds for bone tissue engineering demonstrate biodegradable and bioresorbable characteristics to facilitate new tissue formation (Pietrzak and Ronk, 2000; Yuan *et al.*, 2000; Hench *et al.*, 2004).

To integrate natural biological mechanisms of ECM remodeling, a new class of hydrogels that degrade in response to proteases have been developed (Gobin and West, 2002; Lutolf *et al.*, 2003a). In these scaffolds, degradation occurs through cellular proteolytic activities mediated by enzymes such as collagenase and plasmin. In one of these studies, a poly(ethylene glycol) (PEG) hydrogel modified with adhesion ligands was cross-linked with molecules containing matrix metalloproteinase (MMP) peptide substrates. Migration of human primary fibroblasts inside the gel was observed and found to be dependent on the substrate sensitivity to the enzyme (Lutolf *et al.*, 2003b). When used for delivering recombinant human bone morphogenetic protein-2 (rhBMP-2) into critical-sized defects in rat crania, the PEG hydrogel matrix was remodeled through the MMP-mediated mechanism and supported bone regeneration within five weeks (Lutolf *et al.*, 2003c). The approach demonstrated a paradigm of how scaffold degradation and intervention can be engineered to synchronize with wound healing and new tissue synthesis via natural mechanisms.

### Delivery of Soluble Bioactive Factors

The incorporation of delivery systems in 3D scaffolds offers an indispensable platform for enabling temporal and spatial control in tissue constructs. Compared to systemic administration, using a local controlled-release system to deliver soluble inductive and therapeutic factors has the advantages of preventing rapid factor clearance, metering factors in a desired pharmacokinetic manner, and allowing therapeutic doses for an appropriate duration while limiting

side effects at unwanted body locations. Although numerous material-based controlled-release systems are at the disposal of tissue engineers, most of them need to be adapted when applied to tissue scaffolds. The release of soluble factors from scaffolds can be mediated through single or multiple mechanisms, e.g., by diffusion, dissolution, scaffold or carrier degradation, or external stimuli. In particular, delivery of growth factors has been studied for various tissues, due to their important roles in instructing cell behavior.

Built on established particle-based delivery systems, one common method for controlling the release from a scaffold involves prefabricating biofactor-loaded particles and embedding them into a scaffold matrix (Hedberg *et al.*, 2002; J. E. Lee *et al.*, 2004). The release of biofactors in these systems can be delayed with a minimized burst effect, compared to the particles used alone. Typical particle carriers include PLGA and hydrogel microspheres. This method takes advantage of established systems but involves double matrices, which influence the release profile. Alternatively, soluble factors may be incorporated directly into the scaffold itself without a secondary carrier/matrix. This often requires the scaffold to be fabricated under mild physiological conditions to preserve the bioactivity of proteins or other biofactors. Growth factors and proteins have been incorporated in scaffolds through surface coating (Park *et al.*, 1998), emulsion freezing-drying (Whang *et al.*, 2000), gas-foaming/particulate leaching (Murphy *et al.*, 2000; Jang and Shea, 2003), and nanofiber electrospinning (Luu *et al.*, 2003; Z. Ma *et al.*, 2005). Different delivery profiles of growth factors or DNA plasmids were achieved. Due to their hydrophilic and biocompatible nature, hydrogel scaffolds are amenable to incorporating proteins and plasmid DNA, yielding both higher loading efficiencies and bioactivity as compared to PLGA-based materials. Biofactors have been immobilized in hydrogel matrices via physical interactions and/or covalent chemical bonds for prolonging retention time and controlling release via designed mechanisms (Sakiyama-Elbert and Hubbell, 2000; Tabata, 2003).

Scaffolds that integrate controlled-release methods have been used in conjunction with scaffolds for a variety of purposes, including enhancing tissue formation, stimulating angiogenesis, guiding cell differentiation, and facilitating wound healing (Babensee *et al.*, 2000; Tabata, 2003). Delivering growth factors from scaffolds has demonstrated advantages over using the free form directly (Yamamoto *et al.*, 2000). Synergistic effects on accelerating tissue regeneration have been observed when scaffolds, cells, and growth factors are combined. For example, autologous bone marrow-derived cells transplanted with scaffolds containing bone morphogenetic protein-7 resulted in the greatest bone formation as compared to constructs without either growth factor or cells (Borden *et al.*, 2004). A major challenge in delivering biofactors involves achieving meaningful

pharmacokinetic delivery. The dosage, release kinetics, and duration time should be optimized and tailored to tissue growth/healing mechanisms. For example, VEGF acts as an initiator of angiogenesis, while PDGF provides essential stimuli for blood vessel maturation. To simulate the process, PLGA-based scaffolds have been developed to deliver these two angiogenic factors with distinctive kinetics for rapid formation of a mature vascular network (Richardson *et al.*, 2001).

Instead of releasing soluble growth factors directly into the environment, they can also be initiated by cellular activities. Many growth factors are tightly sequestered in the ECM as inactive precursors and released through their interaction with cells via specific protease-mediated mechanisms. To simulate the biological process, growth factors were covalently conjugated to hydrogel matrices via proteolytically cleavable linkages. The immobilized growth factors remained active, and their release was elicited by cells through plasmin activity (Sakiyama-Elbert *et al.*, 2001; Zisch *et al.*, 2003). In these systems, the mode of growth factor release could be varied and controlled by cellular activities to achieve precise temporal control in different clinical situations.

### Spatial Control

Tissues consist of hierarchically ordered structures of cells and ECM; an important tissue-engineering design principle is incorporating spatial cues into 3D scaffolds to guide structural tissue formation. Such guidance involves designing anisotropic scaffold properties. By generating directional variations in cell–cell and cell–ECM communications, various cell behaviors and new ECM depositions can potentially be guided.

At the macroscopic or tissue level, scaffolds are configured to have appropriate geometries that correspond to tissue/organ anatomical features. The scaffolds are seeded with cells and/or direct the ingrowth of cells from host tissues to promote spatially compartmentalized new tissue growth and wound healing. One of the first methods introduced to generate macroscopic, anatomical shapes utilized highly interconnected pore structures from laminating porous membranes of PLLA and PLGA (Mikos *et al.*, 1993). In another example, polymeric conduits were constructed for growing blood vessels and guiding nerve tissue regeneration. Smooth muscle cells and endothelial cells have been seeded onto tubular biodegradable PGA scaffolds as an approach for engineering vascular grafts (Niklason *et al.*, 1999). Nerve-guidance channels are used for connecting damaged nerve stumps. The entubulation strategy has demonstrated abilities to guide axonal spouting, directing growth-factor diffusion, and blocking undesired fibrous-tissue ingrowth. To fabricate scaffolds with more complex shapes, rapid-prototyping techniques use tissue or defect images recorded by medical imaging modalities, such as

computed tomography (CT) and magnetic resonance imaging (MRI) (Hutmacher, 2001; S. Yang *et al.*, 2002; Hollister, 2005). Another approach to shape scaffold materials to fit into individual tissue defects relies on the liquid–solid transformation process. *In situ* forming hydrogels solidify on external stimuli (e.g., chemicals, light, and pH) and have been designed as injectable scaffolds for minimally invasive cell and biomolecule transplantation. For example, methacrylated PEG and HA polymers were able to photopolymerize *in situ* with chondrocytes and support neocartilage formation *in vivo* (Elisseff *et al.*, 1999; Burdick *et al.*, 2005).

At the microscopic or cellular level, various techniques have been developed to couple cell-/tissue-guidance mechanisms to regenerate tissues that require directional cell growth (e.g., nerve). Anisotropic characteristics in pore architectures, mechanics, surface properties, degradation, and delivery can potentially generate signals recapitulating haptotaxis and chemotaxis for guiding cell behavior and ECM deposition in 3D. Various scaffolds have been developed containing aligned longitudinal regions. For example, PLGA conduit devices containing physical channels have been created by low-pressure injection molding; oriented lumen surfaces facilitated and guided Schwann cell attachment for peripheral nerve regeneration (Hadlock *et al.*, 2000). Guidance can also be generated through fibrous topographical features. Aligned nanofibers made of poly(L-lactide-*co*- $\epsilon$ -caprolactone) were fabricated by an electrospinning technique, and the oriented fiber structure elicited directional growth of smooth muscle cells. Fibrils in natural scaffold materials, such as collagen and fibrin, have been aligned using magnetic fields (Dubey *et al.*, 1999, 2001). The resulting scaffolds increased the rate and depth of axonal elongation *in vitro* and improved sciatic nerve regeneration *in vivo* as compared to scaffolds with random fiber orientations (Dubey *et al.*, 1999).

Creating heterogeneous chemistry in scaffolds is another approach that has been explored to achieve spatial control for tissue guidance. Adhesive RGD peptides have been photoimmobilized in selected regions of agarose hydrogel matrices (Luo and Shoichet, 2004). The patterns of adhesive and nonadhesive regions induced oriented axonal elongation and migration from dorsal root ganglion cell aggregates *in vitro*. Studies have also been carried out to incorporate chemical gradients in scaffolds. Gradients of proteins play important roles in tissue formation/remodeling during embryogenesis and wound healing. Combining fluidic systems and *in situ* forming hydrogel materials, concentration gradients of peptides and proteins have been generated in 3D matrices and exhibited abilities to modu-

late cell functions. For example, entrapment of nerve growth factor in a poly(2-hydroxyethyl methacrylate) hydrogel induced directional axonal growth from PC12 cells *in vitro* (Kapur and Shoichet, 2004). A microfluidic device was used to create gradients of immobilized molecules and cross-linking densities in photo-cross-linked hydrogels; the gradients of immobilized RGD adhesion ligands modulated the spatial distribution of attached endothelial cells (Burdick *et al.*, 2004).

Creating spatial features involves processing of scaffolds to integrate different control mechanisms. To this end, biomaterials with improved processing may need to be combined with different fabrication techniques so that architectural structures, biomolecules, and cells can all be combined in a desired manner. For example, to generate complex tissue patterns, it is desirable to position cells with defined microstructures. Encapsulation of cells using photopolymerizable hydrogel materials has been combined with stereolithography in rapid prototyping to create programmed cell organization in 3D (Tsang and Bhatia, 2004). In designing devices for spinal cord injury repair, as molecular-, cellular-, and tissue-level treatments are discovered, the combinations of such treatments will be necessary to synergistically promote tissue regeneration. Multiple-channel, biodegradable scaffolds have been fabricated with capabilities locally to deliver molecular agents and control cell spatial distribution for transplantation (Moore *et al.*, 2006).

### III. CONCLUSIONS

Tissue-engineering scaffolds need to be built with functions to interact with cells at different spatial and temporal scales to invoke complex, tissuelike patterns. Since the mid-1980s, scaffold design criteria have evolved from simply inducing tissue formation to explicitly controlling tissue formation. Tissue engineers have at their disposal an ever-broadening array of techniques to fabricate scaffolds incorporating spatially and temporally varying biochemical and physical cues. Based on our collective understanding of natural cellular and tissue processes, optimal integration of these scaffold structures and properties should in principle allow us to explicitly control the tissue formation process. The challenge, therefore, is to develop a system-level understanding of how fundamental scaffold properties (e.g., mass transport, mechanics, electrical conductivity, and surface properties) are interrelated in affecting cell behavior and how they can be rationally programmed — spatially and temporally — to provide the necessary signals at the right time and place to aid tissue formation/regeneration.

### I. INTRODUCTION

The fetus is, arguably, the quintessential subject for tissue engineering, both as a host and as a donor. The developmental and long-term impacts of tissue implantations into a fetus, along with the many unique characteristics of fetal cells, add new dimensions that greatly expand the reach of tissue engineering, to extents unmatched by most other age groups. Indeed, perhaps not surprisingly, attempts at harnessing these prospective benefits started long before the modern era of transplantation. The first reported transplantation of human fetal tissue took place in 1922, when a fetal adrenal graft was transplanted into a patient with Addison's disease (Hurst *et al.*, 1922). A few years later, in 1928, fetal pancreatic cells were transplanted in an effort to treat diabetes mellitus. In 1957, a fetal bone marrow transplantation program was first undertaken. All those initial experiments involving human fetal tissue transplantation failed. It was only since around 1980 that fetal tissue transplantation in humans started to yield favorable outcomes. A number of therapeutic applications of fetal tissue have already been explored, with variable results. Although the majority of studies to date have simply involved fetal cell, tissue, or organ transplantation, a number of engineered open systems

using fetal cells have been explored in animal models, and their first clinical applications are seemingly imminent.

Fetal tissue has also been utilized as a valuable investigational tool in biomedical science since the 1930s. Embryologists, anatomists, and physiologists have long studied fetal metabolism, feto-placental unit function, premature life support, and brain activity in previable fetuses. *In vitro* applications of fetal tissue are well established and somewhat common. Cultures of different fetal cell lines, as well as commercial preparations of human fetal tissue, have been routinely used in the study of normal human development and neoplasias, in genetic diagnosis, in viral isolation and culture, and to produce vaccines. Biotechnology, pharmaceutical, and cosmetic companies have employed fetal cells and extraembryonic structures, such as placenta, amnion, and the umbilical cord, to develop new products and to screen them for toxicity, teratogenicity, and carcinogenicity. Fetal tissue banks have been operating in the United States and abroad for many years as a source of various fetal cell lines for research.

Considering that a large body of data has come out of research involving fetal cells or tissues and that attempts at engineering virtually every mammalian tissue have already

taken place, comparatively little has been done on the true engineering of fetal tissue, through culture and placement of fetal cells into matrices or membranes or through other *in vitro* manipulations prior to implantation. Human trials of open-system tissue engineering have yet to be performed, and a relatively small number of animal experiments have been reported thus far. Fetal cells were first used experimentally in engineered constructs by Vacanti *et al.* (1988). Interestingly, this investigation was part of the introductory study on selective cell transplantation using bioabsorbable, synthetic polymers as matrices. This same group performed another study involving fetal cells in 1995 (Cusick *et al.*, 1995). Both experiments, in rodents, did not include structural replacement or functional studies. The use of fetal constructs as a means of structural and functional replacement in large animal models was first reported experimentally only in 1997 (Fauza *et al.*, 1998a, 1998b).

This chapter offers a look at the still-infantile field of fetal tissue engineering along with a general overview of fetal cell and tissue transplantation.

## II. GENERAL CHARACTERISTICS OF FETAL CELLS

Immunological rejection (in nonautologous applications), growth limitations, differentiation and function restraints, incorporation barriers, and cell/tissue delivery difficulties are all well-known complications of tissue engineering. Many of those problems can be better managed, if not totally prevented, when fetal cells are used. Due to their properties both *in vitro* and *in vivo*, fetal cells are an excellent raw material for tissue engineering.

### *In Vitro*

Compared with cells harvested postnatally, most fetal cells multiply more rapidly and more often in culture. Depending on the cell line considered, however, this increased proliferation is more or less pronounced or, in a few cases, not evident at all. Due, at least in part, to their proliferation and differentiation capacities, fetal cells have long been recognized as ideal targets for gene transfers.

Because they are very plastic in their differentiation potential, fetal cells respond better than mature cells to environmental cues. Data from fetal myoblasts and osteoblasts and mesenchymal amniocytes suggest that purposeful manipulations in culture or in a bioreactor can be designed to steer fetal cells to produce improved constructs. Younger mesenchymal stem cells (MSC) from midgestational fetal tissues are more plastic and grow faster than adult, bone marrow–derived MSC. Mesenchymal stem cells have also been isolated earlier in fetal development, from first-trimester blood, liver, and bone marrow. These cells are biologically closer to embryonic stem cells and have unique markers and characteristics not found in adult bone marrow MSC, which are potentially advantageous for cell

therapy. Fetal MSC typically express HLA class I but not HLA class II. The presence of interferon gamma (IFN-gamma) in the growth medium could initiate the intracellular synthesis and cell surface expression of HLA class II, but neither undifferentiated nor differentiated fetal MSC induced proliferation of allogeneic lymphocytes in mixed cultures. Actually, fetal MSC treated with IFN-gamma suppressed alloreactive lymphocytes in this setting. These data indicate that both undifferentiated and differentiated fetal MSC may not elicit much alloreactive lymphocyte proliferation, thus potentially rendering these cells particularly suitable for heterologous transplantation.

Fetal cells can survive at lower oxygen tensions than those tolerated by mature cells and are therefore more resistant to ischemia during *in vitro* manipulations. They also commonly lack long extensions and strong intercellular adhesions. Probably because of those characteristics, fetal cells display better survival after refrigeration and cryopreservation protocols when compared with adult cells. This enhanced endurance during cryopreservation, however, seems to be tissue specific. For instance, data from primates and humans have shown that fetal hematopoietic stem cells, as well as fetal lung, kidney, intestine, thyroid, and brain tissues, can be well preserved at low temperatures, whereas nonhematopoietic liver and spleen tissues can also be cryopreserved, but not as easily.

### *In Vivo*

The expression of major histocompatibility complex (H-2) antigens in the fetus and, hence, fetal allograft survival in immunocompetent recipients is age and tissue specific. The same applies to fetal allograft growth, maturation, and function. At least in fetal mice, the precise gestational time of detection of H-2 antigen expression and the proportion of cells expressing these determinants depend on inbred strain, specific haplotype, tissue of origin, and antiserum batch employed. Nevertheless, the precise factors governing the timing and tissue specificity of H-2 antigen expression are yet to be determined in most species, including humans.

Other mechanisms, in addition to H-2 antigen expression, also seem to govern fetal immunogenicity. It has been suggested that, by catabolizing tryptophan, the mammalian conceptus suppresses T-cell activity and defends itself against rejection by the mother. Fetal cells can be found in the maternal circulation in most human pregnancies, and fetal progenitor cells have been found to persist in the circulation of women decades after childbirth (Bianchi *et al.*, 2002). Interestingly, a novel population of fetal cells, the so-called pregnancy-associated progenitor cells (PAPC), appears to differentiate in diseased/injured maternal tissue. The precise original phenotypical identity of these cells remains unknown. They are thought to be a hematopoietic stem cell, a mesenchymal stem cell, or possibly a novel cell type. What is known is that pregnancy results in the acquisi-

tion of cells with stem-cell-like properties that may influence maternal health postpartum, by triggering disease and/or avoiding/combating it.

These data allow us to suppose that engineered constructs made with fetal cells should be less susceptible to rejection in allogeneic applications. Xenograft implantations may also become viable, for studies suggest that fetal cells are also better tolerated in cross-species transplantations, including in humans (Liechty *et al.*, 2000).

On the other hand, while less immunogenic, some fetal cells may be too immature and functionally limited if harvested too early. Yet experimental models of fetal islet pancreatic cell transplantation have shown that, with time, the initially immature and functionally limited cells will grow, develop, and eventually function normally. Conversely, however, certain cells, such as those from the rat's striatum, actually function better after implantation if harvested early, as opposed to late, in gestation.

Fetal cells may produce high levels of angiogenic and trophic factors, which enhance their ability to grow once grafted. By the same token, those factors may also facilitate regeneration of surrounding host tissues. Interestingly, significant clinical and hematological improvement has been described following fetal liver stem cell transplantation in humans, even when there is no evidence of engraftment. These improvements have been attributed to regeneration of autologous hematopoiesis and inhibition of tumor cell growth promoted by the infused cells, through mechanisms yet to be determined. The underdifferentiated state of fetal cells also optimizes engraftment, by allowing them to grow, elongate, migrate, and establish functional connections with other cells.

### Applications

Because of all the general benefits derived from the use of fetal cells, along with others specific to each cell line, several types of fetal cellular transplantation have been investigated experimentally or employed in humans for decades now. Clinically, fetal cells have been (mostly anecdotally) useful in a number of different conditions, including: Parkinson's disease and Huntington's disease; diabetes mellitus; aplastic anemia; Wiskott-Aldrich syndrome; thymic aplasia (DiGeorge syndrome) and thymic hypoplasia with abnormal immunoglobulin syndrome (Nezelof syndrome); thalassemia; Fanconi anemia; acute myelogenous and lymphoblastic leukemia; Philadelphia chromosome-positive chronic myeloid leukemia; X-linked lymphoproliferative syndrome; neuroblastoma; severe combined immunodeficiency disease; hemophilia; osteogenesis imperfecta; skin reconstruction; acute fatty liver of pregnancy; and neurosensory hypoacusis. They have also been applied to treat inborn errors of metabolism, including Gaucher's disease, Fabry's disease, fucosidosis, Hurler's syndrome, metachromatic leukodystrophy, Hunter's syndrome, glycogenosis, Sanfilippo's syndrome, Morquio syn-

drome type B, and Niemann-Pick disease. Experimentally, fetal cell and organ transplantation has been studied in an ever-expanding array of diseases. *In utero* hematopoietic stem cell transplantation is a promising approach for the treatment of a variety of genetic disorders. The rationale is to take advantage of prenatal hematopoietic and immunological ontogeny to facilitate allogeneic hematopoietic engraftment (Flake, 2004). It is an entirely nonmyeloablative approach to achieve mixed hematopoietic chimerism and associated donor-specific tolerance. Nonetheless, actual fetal tissue engineering as a therapeutic means has barely started to be explored, with comparatively few studies undertaken thus far.

## III. FETAL TISSUE ENGINEERING

Vacanti *et al.* (1988) were the first to make use of fetal cells in engineered constructs. The experiment, in rats, used fetal cells from the liver, intestine, and pancreas, which were cultured, seeded on bioabsorbable matrices, and later implanted. The fetal constructs were implanted in heterologous fashion and heterotopically, namely in the interscapular fat, omentum, and mesentery, with no structural replacement. They were removed for histological analysis no later than two weeks after implantation. Successful engraftment was observed in some animals that received hepatic and intestinal constructs but in none that received pancreatic ones.

Only in 1995 was a second study performed, by the same group, involving fetal liver constructs, also implanted in heterologous and heterotopic fashion in rats (Cusick *et al.*, 1995). Then fetal hepatocytes were shown to proliferate to a greater extent than adult ones in culture and to yield higher cross-sectional cell area at the implant. As in the first experiment, neither structural replacement studies nor functional studies were included.

Fetal constructs as a means of structural and functional replacement, in autologous fashion, in large animal models, were first reported experimentally in 1997 (Fauza *et al.*, 1998a, 1998b). Those studies introduced a novel concept in perinatal surgery, involving the minimally invasive harvest of fetal cells, which are then used to engineer tissue *in vitro* in parallel to the remainder of gestation, so an infant or a fetus with a prenatally diagnosed birth defect can benefit from having autologous, expanded tissue readily available for surgical implantation in the neonatal period or before birth.

### Congenital Anomalies

Major congenital anomalies are present in approximately 3% of all newborns. Those diseases are responsible for nearly 20% of deaths occurring in the neonatal period and even higher morbidity rates during childhood. By definition, birth defects entail loss and/or malformation of tissues or organs. Treatment of many of those congenital anomalies is often hindered by the scarce availability of

normal tissues or organs, either in autologous or allogeneic fashion, mainly at birth. Autologous grafting is frequently not an option in newborns, due to donor site size limitations, and the well-known severe donor shortage observed in practically all areas of transplantation is even more critical during the neonatal period.

Although yet to be fully explored, several studies utilizing fetal tissue engineering as a means to treat congenital anomalies have already been reported in large-animal models (Fauza *et al.*, 1998a, 1998b, 2001; Kaviani *et al.*, 2001, 2002b, 2003; Fuchs *et al.*, 2002, 2003a, 2003b, 2004, 2005, 2006; Krupnick *et al.*, 2004; Kunisaki *et al.*, 2006a, 2006, 2006d). So far, these studies have involved different models of congenital anomalies/structural replacements, involving the skin, bladder, trachea, diaphragm, myocardium, blood vessels, and chest wall. However, many other anomalies are likely to benefit from this therapeutic principle. The first clinical application of fetal tissue engineering is thought to be imminent.

### Alternative Sources of Fetal Cells

In the experiments reported thus far, fetal cells amenable to processing for tissue engineering have been obtained from a variety of sources besides the fetus. These have included the amniotic fluid, the placenta, and the umbilical cord blood. Of all these sources, the amniotic fluid and the placenta are the least invasive ones for both the mother and the fetus, also because amniocentesis and chorionic villus sampling are widely accepted forms of prenatal diagnostic screening (Fauza, 2004). This is particularly true for the amniotic fluid, in that a diagnostic amniocentesis is routinely offered to any mother with a fetus in whom a structural anomaly has been diagnosed by prenatal imaging (Fig. 26.1).

Many amniotic and placental cells share a common origin: the inner cell mass of the morula, which gives rise to the embryo itself, the yolk sac, the mesenchymal core of the chorionic villi, the chorion, and the amnion. Most, if not all, types of progenitor cells that can be isolated from the amniotic fluid and the placenta seem to share many characteristics. However, a common origin of amniotic and placental progenitor cells remains to be unequivocally demonstrated. The full spectrum of cell types that can be obtained from amniotic and placental progenitor cells remains to be determined. In addition, certain fetal pathologic states, such as neural tube and body wall defects, may lead to the availability of cells not normally found in healthy pregnancies, which could be clinically useful.

### Amniotic Fluid

Embryonic and fetal cells from all three germ layers have long been identified in the amniotic fluid (Milunsky, 1979; Hoehn and Salk, 1982; Gosden, 1983; Prusa *et al.*, 2003). However, the specific origins of many subsets of these cell populations remain to be determined. The cellular profile of the amniotic fluid varies with gestational age. In

**FIG. 26.1.** Diagram representing the concept of fetal tissue engineering from amniotic fluid cells for the treatment of birth defects. A small aliquot of amniotic fluid is obtained from a routine amniocentesis, typically performed when a structural anomaly is diagnosed by routine prenatal imaging screening. Fetal tissue is then engineered *in vitro* from amniotic progenitor cells while pregnancy continues, so the newborn or a fetus can benefit from having autologous, expanded tissue promptly available for surgical reconstruction at birth or *in utero*.

addition to the common origin with the mesenchymal portion of the placenta, as mentioned earlier, the amniotic cavity/fluid receives cells shed from the fetus and, quite possibly, from the placenta as well (the latter is yet to be definitely confirmed).

The mechanisms responsible for the production and turnover of the amniotic fluid are thought also to determine the cell types present in the amniotic cavity. In the first half of gestation, most of the amniotic fluid derives from active sodium and chloride transport across the amniotic membrane and fetal skin, with concomitant passive movement of water. In the second half, most of the fluid comes from fetal micturition. An additional substantial source of amniotic fluid is secretion from the respiratory tract. Fetal swallowing and gastrointestinal tract excretions, while not voluminous, also play a role in the composition of the amniotic fluid. As a result of such fluid dynamics, cells present in the urinary, respiratory, and gastrointestinal tracts are shed into the amniotic cavity.

Overall amniotic fluid composition changes predictably throughout gestation. In humans, it is isotonic with fetal plasma in early pregnancy, due to transudation of fetal plasma through the maternal deciduas or through the fetal skin prior to keratinization, which occurs at approximately 24 weeks. Afterwards and until term, it becomes increasingly hypotonic relative to maternal or fetal plasma.

All these variables that play a role in amniotic fluid composition seem to contribute to the changeable profile of the cellular component of the amniotic fluid. Still, much remains to be clarified about the ontogeny of many subsets of amniocytes at any gestational age. This is particularly true before the 12th week of gestation, due, to a large extent, to the limitations of performing amniocentesis before that time.

The fact that certain progenitor cells can be found in the amniotic fluid was apparently first reported in 1993, when small, nucleated, round cells identified as hematopoietic progenitor cells were found therein only before the 12th week of gestation, possibly coming from the yolk sac (Torricelli *et al.*, 1993). A study from 1996 was the first to suggest the possibility of multilineage potential of nonhematopoietic cells present in the amniotic fluid, by demonstrating myogenic conversion of amniocytes (Streubel *et al.*, 1996). That study did not specify the identity of the cells that responded to the myogenic culture conditions, in that case the supernatant of a rhabdomyosarcoma cell line. The presence of mesenchymal cells in the amniotic fluid has been proposed for decades. However, the differentiation potential of mesenchymal amniocytes started to be determined only very recently (Kaviani *et al.*, 2002a; In't Anker *et al.*, 2003; Kunisaki *et al.*, 2006). Likewise, the presence of embryonic-like stem cells in the amniotic fluid was suggested only in the last few years (Coppi *et al.*, 2002; Prusa and Hengstschlager, 2002; Prusa *et al.*, 2003).

Human amniotic epithelial cells have shown pluripotency, being able to differentiate at least into neural and glial cells and into hepatocyte precursors. These cells have been employed therapeutically in animal models of cerebral ischemia and spinal cord injury and as experimental transgene carriers into the liver. However, they are not yet universally considered amniotic fluid cells and will not be discussed further here. Also, given the other, more practical sources of fetal hematopoietic stem cells, other than the difficult pre-12th week amniocentesis, it is unlikely that the amniotic fluid will be a useful option for a source of these cells in clinical practice. Hence, this overview focuses on the mesenchymal and embryonic-like stem cells.

### Mesenchymal Stem Cells

The amniotic fluid is rich in MSC. We have described a very simple protocol for isolation of these mesenchymal amniocytes, based on mechanical separation and natural selection by the culture medium (Kaviani *et al.*, 2001, 2003). Other protocols for isolation of mesenchymal amniocytes have also been described (Hurych *et al.*, 1976; In't Anker *et al.*, 2003). Previous data on amniotic cell culture, without description of the specific nature of the cells grown (possibly predominantly mesenchymal), show that low oxygen tension in the gas phase can be an effective means of enhancing clonal cell expansion (Held and Sonnichsen, 1984). Although not routinely employed, if necessary, molecular HLA typing can be performed on DNA obtained

from expanded MSC, as well as from fetal and maternal blood cells, by polymerase chain reaction/sequence-specific oligonucleotide using a reverse dot blot method, in order to confirm the fetal origin of the cultured cells.

The precise origins of the MSC found in the amniotic fluid remain to be determined. At first, these cells were thought simply to be shed by the fetus at the end of their life cycle. However, they may actually come from the fetus itself and/or the placenta and/or the inner cell mass of the morula, staying viable within the fluid. In no way are mesenchymal amniocytes at the end of their life cycle. Ovine data have shown that amniotic fluid-derived MSC proliferate significantly faster in culture than immunocytochemically comparable cells derived from fetal or adult subcutaneous connective tissue, neonatal bone marrow, and umbilical cord blood (Kaviani *et al.*, 2001; Kunisaki *et al.*, 2006). In humans, the expansion potential of mesenchymal amniocytes exceeds that of bone marrow MSC (In't Anker *et al.*, 2003; Kaviani *et al.*, 2003). The phenotype of human mesenchymal amniocytes expanded *in vitro* is similar to that reported for MSC derived from second-trimester fetal tissue and adult bone marrow (Pittenger *et al.*, 1999; Noort *et al.*, 2002; In't Anker *et al.*, 2003).

Human mesenchymal amniocytes have shown potential for mesodermal differentiation into fibroblasts, adipocytes, chondrocytes, osteocytes, and myogenic lineages after exposure to previously described specific culture conditions (Noort *et al.*, 2002; In't Anker *et al.*, 2003; Kaviani *et al.*, 2003; Zhao *et al.*, 2005; Kunisaki *et al.*, 2006d). The progenitor nature of these cells impart the possibility that they could be used to engineer constructs to correct a wide variety of defects. For example, recent large-animal studies have shown that the repair of congenital diaphragmatic hernia and tracheal defects can be enhanced by the respective use of tendon and cartilaginous grafts engineered from mesenchymal amniocytes during surgical reconstruction (Fig. 26.2 and 26.3) (Fuchs *et al.*, 2004; Kunisaki *et al.*, 2006a, 2006c). Another recently proposed use of an engineered construct based on amniotic mesenchymal (and epithelial) cells is for the repair of premature rupture of membranes during pregnancy, but this has yet to be done *in vivo*.

An intriguing characteristic of mesenchymal amniocytes, at this time studied only in animals, is what seems to be a unique immunological profile, manifest (at least) when they are isolated and expanded *in vitro*. In culture, these cells down-regulate the expression of immune-associated antigens, including MHC-I, when compared to mesenchymal cells obtained from fetal or adult tissue. Hence, mesenchymal amniocytes may be immunologically privileged, when compared to mesenchymal cells derived from fetal or adult tissue.

It has been shown that MSC enhance the engraftment of umbilical cord blood-derived CD34+ hematopoietic cells. The amniotic fluid has recently been proposed as a useful

**FIG. 26.2.** An intact ovine diaphragmatic tendon seen from the chest, 12 months after autologous repair with an engineered, mesenchymal amniocyte-based construct. The dotted line encircles the area of the graft. Reproduced, with permission, from Kunisaki *et al.* (2006c).

**FIG. 26.3.** A representative, cross-sectional view of a 3D cartilaginous tube engineered from mesenchymal amniocytes seeded onto a polyglycolic acid matrix, previously maintained in a bioreactor under chondrogenic conditions.

source of MSC to be cotransplanted with hematopoietic stem cells from the same donor (In't Anker *et al.*, 2003). This could be particularly useful in the setting of umbilical cord blood transplantation between siblings.

*In utero*, transamniotic gene transfer has shown some promise in animal models. Young, highly proliferative, less differentiated fetal cells are natural targets for the optimization of gene therapy. Thus, amniotic and placental stem cells could certainly make useful targets for genetic manipulation. This is a potentially exciting development for the foreseeable future.

### Embryonic-like Stem Cells

From the very little currently known about what could be more primitive, embryonic-like stem cells (ESC) present in the human amniotic fluid, unlike their mesenchymal counterparts, these cells are very scarce, representing 0% (i.e., they cannot always be isolated) to less than 1% of the cells present in amniocentesis samples (Coppi *et al.*, 2002; Prusa and Hengstschlager, 2002; Prusa *et al.*, 2003). In addition, these cells have been identified mostly through markers commonly present in ESC, such as nuclear Oct-4, stem cell factor, vimentin, alkaline phosphatase, CD34, CD105, and cKit, but that were not necessarily concomitantly expressed, nor are they exclusive of ESC proper. Specifically, these markers can also be expressed, alone or in various combinations, in embryonic germ cells; embryonic fibroblasts; embryonal carcinoma cells; mesenchymal stem cells; hematopoietic stem cells; ectodermal, neural, and pancreatic progenitor cells; and fetal and adult nerve tissue; among others. Another marker for human stem cell pluripotency, telomerase activity, has been detected in amniotic fluid cell samples, albeit in a study unrelated to the ones devoted to stem cell isolation (Mosquera *et al.*, 1999).

It is well known that markers alone are not considered enough to characterize human ESC. A uniform and universal differentiation potential needs to be demonstrated, which remains to be verified in these so-called amniotic ESC. So far, some of the amniotic cells that express the markers just mentioned have been shown to differentiate into muscle, adipogenic, osteogenic, nephrogenic, neural, and endothelial cells but not necessarily from a uniform population of undifferentiated cells (Coppi *et al.*, 2002). On the other hand, in accordance with an ESC profile, these pluripotent cells seem to be clonogenic, for at least the Oc-4 positive ones express cyclin A, a cell cycle regulator (Hengstschlager *et al.*, 1999; Prusa *et al.*, 2003). Therefore, although the data currently available can indeed be considered promising, final proof that true ESC can be consistently isolated from the amniotic fluid, and at which gestational ages, remains to be established.

### Placenta

Different cell types are found in the placenta at different gestational ages, as a result of the mechanisms behind pla-

central development. In humans, placental villous development starts between 12 and 18 days postconception (p.c.), when the trophoblastic trabeculae of the placental anlage proliferate and form trophoblastic protrusions, the primary villi, into the maternal blood surrounding the trabeculae. Two days later, embryonic connective tissue from the extra-embryonic mesenchyme invades these villi, which then become secondary villi. Between days 18 and 20 p.c., the first fetal capillaries begin to appear in the now-abundant mesenchyme of the villous stroma, marking the development of the tertiary villi, the first generation of which are the mesenchymal villi. Mesenchymal villi are the first structures providing the morphological requisites for materno-fetal exchange of gases, nutrients, and waste. They are also the precursors of all other villous types, namely immature intermediate villi, stem villi, mature intermediate villi, and terminal villi. At approximately the fifth week p.c., all placental villi are of the mesenchymal type. From about the 23rd week p.c. until term, the pattern of villous growth changes, with the mesenchymal villi transforming into mature intermediate villi, rather than into immature ones. During that phase, few mesenchymal and immature intermediate villi remain, in the centers of the villous trees, where they comprise a poorly differentiated growth reserve.

As shown earlier, placental villous sprouting entails active growth of both trophoblastic and mesenchymal tissue components in a coordinated fashion. Further differentiation of the mesenchymal villi into immature or mature intermediate villi is a determining factor in the balance between growth and maturation of the placenta, which, in turn, has a direct impact on the cell types that can be isolated from the placenta at different gestational ages.

The genetic and molecular mechanisms behind placental development have hardly begun to be clarified and should also have a bearing on the pluripotency of placental cells. Interestingly, against the conventional wisdom of searching for placental-specific genes that would control this process, most of the genes that have been shown to be essential for placental development are also involved in the development of other organs. No more than a very limited set of genes is expressed exclusively in the placenta.

Since much of the placenta comes from the inner cell mass of the morula, the presence of embryonic progenitor cells in the placenta has long been proposed (Crane and Cheung, 1988). More specific types of stem cells, such as trophoblastic, hematopoietic, and mesenchymal stem cells, have also been identified in the placenta for many years. Trophoblast stem cells, also known as trophoendoderm stem cells, are defined as cells with the potential to give rise to all differentiated trophoblast cell subtypes as well as to yolk sac phenotypes. Interestingly, one trophoblast subpopulation, the cytotrophoblasts of the basal decidua, may undergo a full transition to mesenchymal phenotype when they infiltrate maternal mesenchymally derived uterine stroma and arterial walls. At present, trophoblast stem cells

have limited, if any, foreseeable potential for clinical application and will not be reviewed here. Placental/umbilical hematopoietic stem cells have already shown high clinical relevance, but they can also be isolated from umbilical cord blood and are reviewed in another chapter. Placental mesenchymal and embryonic stem cells are further discussed next.

### *Mesenchymal Stem Cells*

As described earlier, the placenta has a large mesenchymal component. While its role in placental development remains to be better understood, we already know that it relates, in part, to the pluripotent potential of placental mesenchymal cells. For example, recruitment of these cells supports the so-called vasculogenesis that occurs during vascularization of the villous sprouts, in addition to the angiogenesis based on the proliferation of endothelial precursors. These mesenchymal cells also play other roles in placental development, such as the paracrine signals that they send to control the stability of the cytotrophoblast column, which in turn determines the degree of trophoblast invasiveness. Yet, much about the mesenchymal core of the placenta remains to be elucidated.

Placental mesenchymal cells can be isolated by a number of different protocols (Haigh *et al.*, 1999; Kaviani *et al.*, 2002b; Romanov *et al.*, 2003). We have described an easy method, analog to the one described earlier for the separation of mesenchymal amniocytes (i.e., based on mechanical separation and natural selection by the culture medium), which can be employed in both “full-thickness” and chorionic villus sampling placental specimens (Kaviani *et al.*, 2002b). These cells have unique characteristics, when compared to other mesenchymal cells. They proliferate more quickly in culture than comparable cells harvested from fetal or adult tissue, at a similar rate to that of mesenchymal amniocytes. Also like mesenchymal amniocytes, they are often stained by monoclonal cytokeratin antibodies, which is a rare finding in mature mesenchymal cells but common in fetal and umbilical stroma, smooth muscle tumors, and stromal cells associated with reactive processes. It is as yet unclear whether this immunoreactivity is a result of cross-reactivity between a common epitope found in smooth muscle cells, myofibroblasts, and intermediate-sized filaments of cytokeratin or whether it actually indicates cytokeratin expression in nonepithelial cells.

In addition to their natural differentiation into smooth muscle cells during placental development, placental mesenchymal cells have been shown to be able to differentiate into all mesodermal cell lineages, as well as some neural cells lineages, *in vitro* (Portmann-Lanz *et al.*, 2006; Zhang *et al.*, 2006). Given the many similarities between placental mesenchymal cells and mesenchymal amniocytes, as shown earlier, it is reasonable to speculate that these two cell subsets are actually the same. This, however, remains to be unequivocally demonstrated.

### Embryonic-like Stem Cells

The embryonic origins of the placenta render it a natural candidate for a reservoir of ESC (Crane and Cheung, 1988). From the few reported attempts to isolate ESC from the placenta, like their amniotic counterparts, what could be ESC are present in 0% to less than 1% of the cells present in placental samples (Coppi *et al.*, 2002). These cells have also been identified mostly through certain markers, including CD34, CD105, and cKit, that, again, were not necessarily concomitantly expressed and are not exclusive of ESC.

These pluripotent cells have shown potential for self-renewal, but a uniform and universal differentiation potential of these cells also remains to be verified. Like their amniotic counterparts, thus far some of these cells have been shown to differentiate into a variety of cell types, but not necessarily from a uniform population of undifferentiated cells. Another limitation of the existing data is the fact that the placenta is rich in hematopoietic stem cells, known not to be committed solely to the hematopoietic lineage. In addition to blood cells, they can give rise, at least, to neurons, hepatocytes, and muscle cells and might have contributed to the differentiation findings reported to date. Again, although the existing data are promising and in accordance with the origins of the placenta, final proof that true ESC can be consistently isolated from that organ, and at which gestational ages, remains to be verified.

Another interesting potential development of the study of placental cells is the establishment of 3D models of the placenta and of maternal-fetal circulation through the maintenance of live engineered placental models in bioreactors (Ma *et al.*, 1999). This could lead to a better understanding of normal and pathological placental physiology, possibly with indirect therapeutic benefits.

## IV. ETHICAL CONSIDERATIONS

The use of fetal tissue has always been object of intense ethical debate. The main reason for the ethical controversies comes from the fact that the primary source of fetal tissue is induced abortion. Spontaneous abortion usually does not raise many moral issues. The National Institutes of Health, the American Obstetrical and Gynecological Society, and the American Fertility Society, in accordance with the provisions that control the use of adult human tissue, have long regulated the use of fetal specimens from this latter source. However, spontaneous abortion generally yields unsuitable fetal tissue, for it is frequently compromised by pathology such as chromosomal abnormalities, infections, and/or anoxia. Arguments on the use of fetal tissue from induced abortion are based largely on somewhat limited scientific evidence, along with clashing religious and customary beliefs about the beginning of life. Not surprisingly, despite the efforts of numerous national and international ethical committees and governmental bodies, a consensus has not

yet been reached. In the United States, in spite (or perhaps because) of an ongoing moratorium on federal funding for fetal tissue transplantation research, an agreement on this issue may be forming slowly, though a stable solution could still be years away.

This polemic notwithstanding, tissue engineering, as a novel development in fetal tissue processing, adds a new dimension to the discussion concerning the use of fetal tissue for therapeutic or research purposes. If specimens from a live, diseased fetus or cells from a routine prenatal diagnostic procedure such as an amniocentesis or chorionic villus sampling are to be used for the engineering of tissue, which, in turn, is to be implanted in autologous fashion, then no ethical objections should be anticipated, as long as the procedure is a valid therapeutic choice for a given perinatal condition. In that scenario, ethical considerations are the very same that apply to any fetal intervention. On the other hand, if fetal engineered tissue is to be implanted in heterologous fashion, ethical issues are analog to the ones involving fetal tissue/organ transplantation, regardless of whether the original specimen comes from a live or deceased fetus or from banked fetal cells obtained from the amniotic, placenta, or umbilical cord blood.

The distinction between autologous and heterologous implantation of engineered fetal tissue is a critical one, in that, again, no condemnation of autologous use could be ethically justified. At the same time, regardless of whether an autologous or heterologous application is being considered, should the amniotic fluid or the placenta be definitely confirmed as dependable sources of ESC, then the ethical objections to embryo disposal now plaguing the progress of ESC research could possibly be avoided.

## V. THE FETUS AS A TRANSPLANTATION HOST

One could envision a number of advantages of a fetus receiving an engineered construct *in utero*, not only from a theoretical perspective but also from clinical and experimental evidence derived from intrauterine cellular transplantation studies already reported. Those potential advantages encompass induction of graft tolerance in the fetus, due to its immunologic immaturity; induction of donor-specific tolerance in the fetus by concurrent or previous intrauterine transplantation of hematopoietic progenitor cells; a completely sterile environment; the presence of hormones, cytokines, and other intercellular signaling factors that may enhance graft survival and development; the unique wound-healing properties of the fetus; and early prevention of clinical manifestations of disease, before they can cause irreversible damage. Most of those advantages should be more or less evident, depending on the gestational timing of transplantation.

### Fetal Immune Development

Among the potential benefits of *in utero* transplantation, the singularity of the fetal immune system deserves special attention. In that respect, basic research on fetal development as well as studies involving pre- and postnatal transplantation of lymphohematopoietic fetal cells have contributed to a better understanding of the fetal immune response.

For almost a century now, fetal tolerance resulting in permanent chimerism has been known to occur in nature in nonidentical twins with shared placental circulation. Little is known, however, about precisely when and by what mechanism this tolerance is lost. During fetal development, the precursors of the hematopoietic stem cells arise in the yolk sac and migrate to the fetal liver and then to the thymus, spleen, and bone marrow. The fetal liver has its highest concentration of hematopoietic stem cells between the 4th and the 20th week of gestation. Because of their cellular immunologic “immaturity,” the fetal liver and, to a lesser extent, the fetal thymus have been studied as potential sources of hematopoietic stem cells for major histocompatibility complex-incompatible bone marrow transplantation for almost four decades now. Umbilical cord blood has been increasingly employed as a source of hematopoietic stem cells, in both autologous and heterologous applications (Benito *et al.*, 2004; Rocha *et al.*, 2005).

Lymphocytes capable of eliciting graft-versus-host disease (GVHD) are found in the thymus by the 14th week of gestation but are not detectable in the liver until the 18th week. Despite considerable numbers of granulocyte-macrophage colony-forming cells, there is an almost complete absence of mature T-cells up to the 14th week in human fetal livers. During gestation, while B-cell development takes place mostly in the liver, T-cell development occurs predominantly in the thymus. This fact is probably the reason why fetal liver cells are immunoincompetent for cell-mediated and T-cell-supported humoral reactions, such as graft rejections and GVHD. Thus, in principle, tissue matching is not necessary in fetal liver transplantation if this is harvested up to a certain point in gestation. In a number of animal models and small clinical series, fetal liver cells have induced no or merely moderate GVHD in histoincompatible donor/recipient pairs.

Umbilical cord blood and placental blood, on the other hand, while rich in hematopoietic progenitor cells, contain alloreactive lymphocytes. Although those lymphocytes are also immature, it is unclear, however, whether they are more or less reactive than adult ones. Compared with those from adult blood, the proportions of activated T-cells and helper-inducer subsets (CD4/29) are significantly reduced, while the helper-suppressor (CD4/45A) subset is significantly increased. Cord blood natural killer cell activity is low or similar to that in adult blood, but lymphokine-activated killer cell activity may be higher.

Although fetal liver stem cells should not cause GVHD, they could still be subject to rejection. Because of that, fetal liver stem cell transplantation has been attempted in the clinical setting preferably in patients with depressed immune function, such as in immunodeficiencies, replacement therapy during bone marrow compromise, and during fetal life (*in utero* transplantation). The same principle applies to the use of fetal thymus. Fatal cases of GVHD are considered much less likely in patients who receive fetal liver stem cells harvested before the 14th week of gestation. This complication, however, has been reported in a patient who received liver cells from a 16-week-old fetus. With umbilical cord blood stem cell transplantation, the incidence of GVHD has been minimal (Benito *et al.*, 2004; Rocha *et al.*, 2005).

### Applications of *In Utero* Transplantation

Cellular intrauterine transplantation has been employed clinically to treat a variety of diseases, including lymphohematopoietic diseases, beta-thalassemia, inborn errors of metabolism, and genetic disorders, with some success. The optimal gestational age for transplantation along with cell selection, route of cell administration, and postinterventional tocolysis is still evolving.

*In utero* hematopoietic stem cell transplantation is a nonmyeloablative approach to achieve mixed hematopoietic chimerism and associated donor-specific tolerance, improving survival of other grafts later in life. Through prenatal transplantation of hematopoietic progenitor cells, both allogeneic and xenogeneic chimerisms have been induced in animal models, and allogeneic chimerism has been achieved in humans. Tolerance of allogeneic intrauterine implantation of an engineered construct has recently been first demonstrated in an ovine model of fetal tracheal reconstruction with heterologous cartilage engineered from amniotic fluid-derived MSC (Kunisaki *et al.*, 2006a). Other potential therapeutical benefits of prenatal implantation of engineered tissue, as well as likely advantages stemming from the commonly scarless fetal wound healing, are yet to be fully explored.

## VI. CONCLUSIONS

Fetal tissue engineering may become a preferred perinatal alternative for the treatment of a number of birth defects. Given the recently proven viability of minimally invasive fetal cell sources, such as amniotic fluid, placenta, and umbilical cord blood, the promise of fetal tissue engineering should apply to both life-threatening and non-life-threatening anomalies. Fetal progenitor cells from various sources are becoming progressively relevant, if not indispensable, tools in research related to stem cells, tissue engineering, gene therapy, and maternal-fetal medicine.

Still, much remains to be learned, and a variety of evolutionary paths, including unsuspected ones, have yet to be

pursued in this relatively new branch of tissue engineering. The whole subfield of *in utero* implantation of engineered tissue also waits to be fully explored. Fetal tissue engineering shall also benefit from the progress expected for the different aspects of tissue engineering in general. Fertile experimental work from an increasing number of groups

has introduced promising novel therapeutic concepts utilizing fetal cells. As long as progress is made in the ethical debate over the use of these cells and their banking, the reach of fetal tissue engineering, nonetheless, will likely go beyond the perinatal period, offering unique therapeutic perspectives for different age groups.

### I. INTRODUCTION

A long-standing goal of the transplant community has been to overcome immunologic rejection of transplanted tissues and organs. Although much of the research has been devoted to identifying new immunosuppressive agents and new combinations of existing agents for allotransplantation, immunosuppression still carries significant long-term side effects, especially enhanced susceptibility to infection. For xenografts, even stronger immunosuppression is necessary. One solution to allograft or xenograft acceptance may reside in novel therapeutic strategies that strive to prevent the need for long-term and high-dose immunosuppression.

Our laboratory has attempted to avert transplant rejection by immunologically modifying the foreign proteins on cells and tissues from the donor, instead of treating the host. Treated tissues and cells before transplantation allow the concealment or elimination of the antigens that summon immune rejection. This technology is sometimes referred to as *donor antigen modification* or, more stylistically, *designer tissue and organs* (Faustman and Coe, 1991). The goal is to avoid or reduce the need for immunosuppression by modi-

fying directly the graft at the molecular or protein level. Modification at the *cellular* level, by eliminating donor lymphoid cell populations, had been previously successful in murine allografts. These cellular modifications were effective for whole organs and cell transplants in lower species, even for the avoidance of xenograft rejection. Designer tissues and organs modified at the *molecular* or *protein* level offer an alternative approach with greater selectivity and latitude in tailoring the graft to escape immune detection by the host.

Without the risks of massive doses of systemic immunosuppression, designer tissues and organs could be therapeutic for a broad range of chronic conditions that are not life threatening. They also could be offered to conventional organ transplant patients at earlier stages of their disease, when patients are healthier and better able to withstand surgical intervention. The main risk with designer tissues and organs is that the modified donor tissue could be rejected, a risk commonly encountered with any transplant. Because designer tissue can potentially be rendered safer and may ultimately avoid host intervention with toxic drugs, a broader spectrum of diseases could be treated and at earlier time points.

The purpose of this chapter is to describe the evolution of research on designer tissues and to trace its contribution to a growing body of transplant research. The first success was with murine hosts given transplants of xenogeneic cells and tissues that had been modified at the *protein* level. The success allowed extension of the concept to the molecular level, in the form of DNA modifications. The ability to modify proteins at the DNA, RNA, or protein level offers tremendous versatility in developing new cells or organs as biological therapies. Variations on the designer tissue concept are being probed in animal models of diabetes, solid organ failure, and neurological diseases. A concept launched in the laboratory in the early 1990s has already culminated in landmark human clinical trials for Parkinson's disease and Huntington's disease using donor-modified pig neurons in humans.

The wide range of applications of designer tissues and organs for allo- and xenotransplantation is readily apparent; modified donor cells, tissues, and organs can be considered potential therapies for an almost limitless number of conditions as long as the dominant antigens are identified and then effectively shielded or eliminated prior to implantation.

## II. ORIGIN OF THE DESIGNER TISSUE CONCEPT

The idea of targeting donor antigens instead of modifying the host immune system was stimulated by research on the molecular events surrounding the killing of cancer cells by cytotoxic T-lymphocytes (CTLs; hereinafter referred to as T-cells). In an elegant study, Spits and co-workers (1986) identified the sequential stages of T-cell destruction of the cancer cell. In contrast to earlier research, which focused primarily on the T-cell, they examined the roles of cell surface markers on both the T-cell and the target cell. By using antibodies against different cell surface markers on the cancer cells, they were able to block distinct obligatory stages of T-cell activation and destruction. They were able to tease apart *in vitro* the interactions between molecules on the T-cell and the target cell. Spits and colleagues were among the first to identify three stages in T-cell cytotoxicity: (1) adhesion between T-cell and target cell through two adhesion proteins, (2) T-cell receptor activation through class I, and (3) T-cell lysis of the tumor target cell through persistent class I and T-cell receptor binding.

A critical finding was that one of the major classes of histocompatibility antigens on the surface of the cancer cell — the major histocompatibility complex (MHC) class I molecules — was involved in both adhesion to and activation of the T-cell. Class I antigens and other classes of antigens encoded by the MHC complex serve to distinguish “self” from “nonself” because they differ across species and between members of the same species. Class I antigens had long been suspected of eliciting T-cell cytotoxicity, but this

study offered more detailed insight into their pivotal role. What this study also demonstrated was that antibodies to class I antigens on the cancer cell could block T-cell adhesion and activation, thereby preventing lysis of the target cell.

Spits and coworkers crystallized the importance of class I antigens in immune rejection of cancer cells. While this study's goal was to dissect and promote CTL killing of the target, our goal was the opposite: to prevent tissue rejection at the same T-cell–target interface. We chose to “mask” class I antigens on donor cells by using antibody fragments to class I, a system that prevented death of the target, and then to transplant the modified donor cells into nonimmunosuppressed hosts.

## III. FIRST DEMONSTRATION OF THE CONCEPT

The first successful demonstration of the designer tissue concept used a xenogeneic model (Faustman and Coe, 1991). The cellular graft, in the form of insulin-secreting islets, was coated with antibody fragments to conceal class I antigens; the grafted cells (of human origin) indefinitely eluded the immune system of the murine host. The grafted cells also functioned normally. The host even developed tolerance to the treated graft because secondary transplants of untreated tissue were later accepted. The mechanism of donor-specific tolerance is still not fully defined, but it may involve induction of T-cell anergy through altered donor class I density. Altered class I density may be pivotal in T-cell shaping in both the periphery as well as the thymus, as defined by Pestano *et al.* (1999).

The graft consisted of purified human cadaveric islets that had been incubated with antibody fragments before being implanted into nonimmunosuppressed mice. Pure antibody fragments that lack the portion of the antibody molecule that binds complement, the Fc fragment, were obligatory to prevent lysis of the target. When the Fc fragment is enzymatically cleaved from the F(ab')<sub>2</sub> fragment, the purified F(ab')<sub>2</sub> fragment binds to the graft for several days without fixing complement; this prevents the graft from being destroyed. Grafts survived for 200 days and functioned appropriately, as determined by assays for human C' peptide, a proinsulin-processing product. Finally, human liver cells similarly treated with antibody fragments also survived for an extended period.

Treatment with whole antibodies to class I antigens failed to prolong graft survival; whole antibody class I proteins coated the donor cell but also, upon transplantation, killed the cell, due to host-derived complement. Treatments with antibodies and antibody fragments to CD29 was effective in an allogeneic transplant barrier using cells but not in a xenogeneic barrier. CD29 is an antigen with restricted expression on the passenger lymphocytes that accompany the graft. Passenger lymphocyte elimination can be impor-

tant for allografts but less important for cross-species transplants. Treatment of cellular grafts with polyclonal antibody fragments to all antigenic determinants prior to transplantation did prolong allograft and xenograft survival. Polyclonal antibody fragments with class I antibody fragment removal had minimal effects at facilitating cellular transplants.

For the sake of rigor, it is generally accepted that xenografts represent a more challenging transplant barrier than allografts. Furthermore, if experimental test concepts are applied to xenografts with success, similarly enhanced allograft survival is likely to ensue. If designer tissues could succeed in a difficult xenogeneic case, then these same procedures could be considered for simpler allogeneic transplant models. Additionally, cellular transplant models represent the intermediate model of simplicity. In the setting of cells, the graft tissue contains one dominant antigen that needs to be masked. For instance, human islet tissue highly expresses class I antigens while displaying only minimal expression of two adhesion molecules, intercellular adhesion molecule-1 (ICAM-1) and lymphocyte function-associated antigen-3 (LFA-3) (which in other tissues are thought to stabilize binding and to contribute to T-cell activation). Second, xenogeneic cellular transplants lack the vasculature that can be separated from the tissue to avoid hyperacute rejection, the earliest and most formidable barrier to discordant xenograft acceptance. Third, targeted antigens at the surface protein level rather than at the genetic level allow greater flexibility and less expense than the creation of genetically engineered pigs. Our goal was to conceal protein antigens that already appeared on the surface of graft cells. Other approaches, discussed later in this chapter, targeted

antigens, not at the protein level, but at the DNA and RNA level. The use of more sophisticated transgenic and antisense technology, respectively, can similarly prevent antigen expression. It also can validate the donor antigens as a target for the immune response.

In summary, this tough xenogeneic model establishes the paramount role of class I antigens on cellular transplants. By providing a challenging test of the designer tissue concept, it also helped to launch a novel therapeutic strategy.

## IV. EXPANSION OF RESEARCH ON DESIGNER TISSUES

The potential of designer tissues to produce tissues and organs with reduced surface proteins can use a variety of donor antigen modification techniques in various transplantation settings. This body of early research is, in part, summarized in Table 27.1 and can be classified by the method that interferes with the expression of the surface protein of interest. The methods to remove or disguise surface proteins in the donor cells can include antibody “masking,” gene ablation, and antisense and enzymatic treatments and are the topic of this chapter.

## V. ANTIBODY MASKING

Antibody masking of xenogeneic tissue is the first of the donor antigen modification techniques to progress to primate and human trials. Pancreatic islet cells and neurons are the most common types of donor cells to be camouflaged with antibody masking, although any type of tissue can theoretically be treated once the dominant antigens

**Table 27.1. Designer donor tissues**

<i>Technique/tissues</i>	<i>Allo/xeno</i>	<i>Donor/recipient</i>	<i>Target</i>	<i>Reference</i>
<b>Masking antibody</b>				
Islets	Xeno	Human/mouse	Class I	Faustman and Coe (1991)
Islets	Xeno	Human/mouse	All surface antigens	Faustman and Coe (1991)
Islets	Allo/xeno	Human or monkey/monkey	Class I	Steele <i>et al.</i> (1994)
Islets	Allo	Mouse/mouse	Class I	Osorio <i>et al.</i> (1994)
Neurons	Xeno	Pig/rat	Class I	Osorio <i>et al.</i> (1994), Pakzaban <i>et al.</i> (1995)
Neurons	Xeno	Pig/monkey	Class I	Burns <i>et al.</i> (1994)
Liver cells	Xeno	Human/mouse	Class I	Faustman and Coe (1991)
<b>Gene ablation</b>				
Islets	Allo	Mouse/mouse	Class I	Markmann <i>et al.</i> (1992)
Islets	Allo	Mouse/mouse	Class I	Osorio <i>et al.</i> (1993)
Islets	Allo	Mouse/mouse	Class I	Osorio <i>et al.</i> (1994a, 1994b, 1994c, 1994d)
Liver cells	Allo/xeno	Mouse/mouse/guinea pig/frog	Class I	Li and Faustman (1993)
Kidneys	Allo	Mouse/mouse	Class I	Coffman <i>et al.</i> (1993)

have been identified. All of the studies cited here targeted class I antigens using antibody fragments and relate to cellular transplants.

Islet cell masking for the treatment of diabetes was early on pursued, with mixed results. Osorio and colleagues (1994a, 1994b, 1994c, 1994d) targeted class I antigens in a mouse allograft model. To approximate a diabetic state, the mice first were treated with a drug that chemically induced hyperglycemia. Then they received islet allografts that had been pretreated with antibody fragments. Graft survival was prolonged relative to controls, but within one month the grafts were eventually rejected. Investigators attributed eventual allograft rejection to a variety of possibilities, including the absence of sufficient quantities of  $F(ab')_2$  fragments, antiidiotypic antibodies against the  $F(ab')_2$  fragment, and an immune pathway independent of class I activation of T-cells. Steele and colleagues (1994) investigated islet cell transplants in a primate model. Cynomolgus monkeys received either allogeneic or xenogeneic (human) islets. The grafts were pretreated with antibody fragments to class I antigens. Histologic evidence revealed that donor islets were present months after transplantation into nonimmunosuppressed monkeys.

Neuronal xenografts with antibody masking have been investigated for Huntington's disease (Pakzaban *et al.*, 1995) and Parkinson's disease (Burns *et al.*, 1994). In the first study, fetal pig striatal cells were implanted into rats whose striatum had been lesioned one week earlier with injections of quinolinic acid. These injections destroy striatal neurons in an attempt to simulate the dysfunction present in Huntington's disease. Rats received either untreated tissue or tissue pretreated with  $F(ab')_2$  fragments against porcine class I antigens. Control rats receiving untreated tissue were either immunosuppressed with immunosuppressant cyclosporin A (CsA) or left untreated. Three to four months later, graft survival was found to be prolonged in animals given  $F(ab')_2$ -treated grafts and in the CsA-treated control animals given unaltered grafts. Grafts did not survive in nonimmunosuppressed controls. Graft volume, determined histologically with the aid of computer image analysis, was significantly larger in the CsA group as compared with the  $F(ab')_2$  group. Yet in both of these groups, immunohistochemistry revealed graft cytoarchitecture to be well organized and graft axons to have grown correctly in the direction of their target nuclei. It was encouraging that pig neurons appeared to be capable of locating their murine target.

In a similar study design, Burns and coworkers (1994) applied antibody masking to a primate model of Parkinson's disease. Porcine mesencephalic neuroblasts were implanted into monkeys with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced Parkinsonism. Measures of locomotor activity and dopamine fiber density in the host striatum confirmed that pretreatment of donor tissue with  $F(ab')_2$  fragments succeeded in restoring motor function

and replenishing dopamine fibers at the site of implantation. A control animal, maintained on CsA after receiving untreated cells, showed similar improvement. A nonimmunosuppressed control showed no improvement after transplantation, suggesting graft rejection.

The studies described in this section highlight the range of potential applications of antibody masking in both allo- and xenotransplants. Neuronal cell masking has been sufficiently effective to usher in human clinical trials.

## VI. GENE ABLATION

Gene ablation, or gene "knockout" technology, offers another vehicle to modify donor tissue and organs. With gene ablation, the gene or genes encoding protein antigens can be permanently deleted, thereby eliminating antigen expression in all cells. In one common method of gene ablation, the target gene is inactivated in cultured embryonic stem cells via homologous recombination; a target vector containing an inactive version of the gene recombines with, and thereby replaces, the wild-type gene. Through reintroduction of the embryonic cells into a foster mother and through selective breeding, progeny can be produced that are homozygous for the mutation. Rejection by the host immune system is expected to be avoided when the targeted gene encodes a protein antigen slated for expression on the surface of donor cells.

The major advantage of gene ablation over protein modification of donor tissue is that the antigen is permanently eliminated in all cells, tissues, and organs in which it is expressed. The major limitation of this technology is that it is restricted to potential xenografts from pigs and requires pig "farming," an expensive, albeit potentially abundant, source of donor tissue. The permanent nature of the modification also can sometimes be a limitation, especially when the protein encoded by the gene has additional functions. Inactivation of the gene might lead to physiological changes that compromise the utility of the donor tissue. Gene ablation can also target genes that encode proteins essential for the target protein expression.

Several transplantation laboratories have exploited the availability of knockout mice deficient in  $\beta_2$ -microglobulin.  $\beta_2$ -microglobulin is a peptide that performs a chaperone function as part of the class I molecule and is necessary for its assembly and expression. Mice homozygous for the  $\beta_2$ -microglobulin mutation fail to display class I antigens on the cell surface, a feature that makes them highly desirable for transplantation studies. Class I ablation through the mutation are not necessarily a permanent depletion of class I, due to host  $\beta_2$ -microglobulin reconstituting the graft. Although much of the research described later has focused on islet cell and liver cell xenotransplants, one project examined whole-organ allografts. Coffman and coworkers (1993) found that kidneys from  $\beta_2$ -microglobulin-deficient mice functioned significantly better in allogeneic recipients than did kidneys from normal mice.

The fate of pancreatic islet transplants from  $\beta_2$ -microglobulin-deficient mice has been explored in several studies. The islets showed prolonged survival when implanted into a normal mouse strain (Markmann *et al.*, 1992; Osorio *et al.*, 1993). Most grafts survived indefinitely (>80% beyond 100 days) and were capable of reversing hyperglycemia that had been chemically induced prior to transplantation. Investigators attributed the few instances of graft rejection to three possibilities. First, some surface expression of class I antigens can occur in the absence of  $\beta_2$ -microglobulin. The presence of even a fraction of the total number of class I antigens may be sufficient for T-cell recognition and lysis. Second,  $\beta_2$ -microglobulin circulating in the serum of the recipient can be used to reconstitute class I antigens on the donor tissue (because  $\beta_2$ -microglobulin is a highly conserved protein not encoded by genes at the MHC locus). Third, rejection of the tissue from  $\beta_2$ -microglobulin-deficient donors may be mediated by other immune pathways, such as by natural killer cells. Support for the second and third possibilities was presented by Li and Faustman (1993) in their study of liver cell allo- and xenografts.

For whole-organ xenografts, it has long been recognized that certain sugars on donor tissues, especially the vascular endothelium, such as gal  $\alpha(1,3)$ galactosyltransferase, have a central role in hyperacute rejection. This hyperacute rejection is mediated by preformed antibodies in disparate species, often referred to as *natural* antibodies (Sandrin and McKenzie, 1994; Sandrin *et al.*, 1993). If hyperacute rejection of whole-organ xenografts can be prevented, then other cellular barriers, such as disparate class I expression, can be addressed.

Given the important role of donor sugar epitopes eliciting rapid organ rejection, knockout pigs were produced, with the first strategy applied to donor antigen modification for this epitope. The pigs had complete elimination of the gene that encoded  $\alpha(1,3)$ galactosyltransferase. To the surprise of the scientific community, the knockout pigs continued to express considerable levels of the carbohydrate sugars.

Therefore, in the pig, more than one genetically encoded enzyme is able successfully to synthesize Gal  $\alpha(1,3)$  gal surface sugars (Milland *et al.*, 2006). These studies demonstrate that although three prior methods can change donor antigen expression in cells, i.e., gene ablation, antisense for RNA, and “masking” antibodies, some methods may have unexpected shortcomings specific to the interruption method.

## VII. RNA ABLATION

RNA ablation is another strategy that strives to prevent antigen expression by blocking gene transcription or translation. RNA ablation can be achieved through the creation of oligodeoxynucleotides that are complementary to, and hybridize with, DNA or RNA sequences to inhibit transcription or translation, respectively.

To date RNA ablation in the transplant field has been less frequently pursued. Ramanathan and coworkers (1994) identified an oligodeoxynucleotide that inhibited induction of class I and ICAM expression by interferon- $\gamma$ . The studies were performed *in vitro* in a cell line, K562, that normally has low-level expression of class I antigens. They first postulated that the oligodeoxynucleotide acted in the early stages of interferon- $\gamma$  induction rather than posttranslationally. In their follow-up study, they showed that the oligodeoxynucleotide acted even earlier via a novel mechanism: It inhibited binding of interferon- $\gamma$  to the cell surface (Ramanathan and Houston, 1984; Ramanathan *et al.*, 1994). This may be an unusual mechanism for an oligodeoxynucleotide, but it only enhances the possibilities for xenotransplant research. RNA ablation, unlike protein modifications with masking or DNA modifications in transgenic donors, offers an additional challenge. For RNA ablation to work, all cells must be treated equally with the interfering RNA. Antisense technology or even newer methods, such as siRNA, often result in uneven distributions of interruptions in the cells or organs. What these studies provide is yet another means of blocking expression of class I antigens or other transplantation antigens.

## VIII. ENZYME ABLATION

Although MHC class I surface structures are extremely polymorphic, the polymorphisms of MHC class I are confined predominantly to the exterior region of the protein and the regions of the protein that are exterior facing. This feature allows the host's immune system, i.e., T-cells, the early opportunity to reject tissues transplanted from unrelated individuals.

As the genome effort has advanced and hundreds of MHC class I alleles of the gene have been sequenced, it has also become apparent that certain regions of the MHC structure are highly polymorphic, in contrast to other regions of the protein that are highly conserved. Even across species, the conserved regions of the MHC allele compose the protein portions that are near and within the cell surface membrane. This conservation of structure is maintained across species as diverse as mice and humans.

The conserved regions of MHC class I within and across species have afforded, in solubilized cells, the opportunity specifically to purify these proteins by enzymatic cleavage. Most typically, cell lysates have been treated with papain to solubilize all MHC structures from the cell surface, usually at very acid pH (Ezquerro *et al.*, 1985). Papain has the remarkable ability to cleave the conserved hydrophilic regions of the class I protein without cleaving other cellular proteins (Springer and Strominger, 1976). Papain's conserved-cleavage feature is preserved for mouse, human, and primate class I alleles.

We have gradually worked with this system in a mouse transplant model to allow papain to cleave class I from all

cells and have the cells remain fully viable at the end of the brief treatment. This MHC class I modification method with pretreatment with papain, with modified buffers at physiological pH, now allows complete class I depletion and subsequent transplantation of cell transplants, with prolonged survival. Survival of the transplanted cells, in the form of insulin-secreting islets or liver cells, is comparable to either methods of genetically ablated class I-deficient tissues or “masked” class I-deficient tissues.

Each method of modifying donor cell surface proteins, such as MHC class I, prior to transplantation has features that are unique to the translation of these methods to clinical trials (Table 27.2). The production of genetically engineered donor pigs permits the generation of abundant tissue, but the donor tissue will be xenografts and thus encounter tough transplant barriers and xenosis risk. Also, the cost of developing the herds of animals is very expensive. The generation of masking antibodies allows the donor tissue modifications to be applied to allografts or xenografts. The masking antibodies are protein fragments and can be designed to different donor HLA types. The production of masking antibodies is easier than the production of genetically engineered pigs but requires manufacturing of a novel

protein fragment and standardization for FDA approval. Also, the preclinical efficacy studies using masking antibodies would be specific for the species chosen, so the translation to human studies would not use the identical antibody fragment. Finally, the use of specific enzymes to cleave off donor antigens, such as MHC class I, is inexpensive to develop, and the same enzyme product could be applied to preclinical murine studies, baboon studies, and human indications. All three donor tissue modifications could be combined with reduced or eliminated immunosuppression, thus increasing the safety margins for cellular transplants for nonlethal diseases.

## IX. MECHANISMS OF GRAFT SURVIVAL AFTER CLASS I DONOR ABLATION OR ANTIBODY MASKING

Research on the ability of class I modified tissues or cells to survive long term without host immunosuppression has been closely studied. Indeed it was appreciated that although the method for altering donor class I expression prior to transplantation could be diverse, i.e., masking antibodies or gene ablation of chaperone proteins or

<sup>a</sup>Antisense or siRNA technology has had limited success in settings of cell or tissue transplantation and thus is not represented in the table as a method for donor antigen modification.

enzymes, a common theme in these models was long-term stable survival of the functioning tissue. The transplants were viable and certainly reexpressed donor class I with the passage of time. Insight into the role of systemic tolerance in these transplants is important for future refinements of cellular transplant methods to optimize success.

Systemic tolerance to the graft was initially addressed for donor tissues with modified class I due to ablation of the class I chaperone protein, i.e.,  $\beta_2$ -microglobulin. First, as the donor and recipient diverge phylogenetically, so does the homology of the  $\beta_2$ -microglobulin proteins. Donor grafts from highly divergent species have slower reconstitution of surface class I with  $\beta_2$ -microglobulin from the host serum and shorter survival times (Hyafil and Strominger, 1979). The shortened survival times as compared to less divergent cross-species transplants suggests that some degree of donor class I antigen expression is beneficial after the transplant is established. Indeed, many have proposed that the intact natural killer cells of the host, a natural defense against class I-deficient tumors, may be the reason for more brisk rejection with more permanent class I depletion.

The reconstitution of donor surface class I with host  $\beta_2$ -microglobulin in the gene ablation model also explains why transient ways of interruption class I allows systemic tolerance. The primary cellular grafts with transient class I interruption permit secondary nongenetically manipulated or non-antibody-masked grafts to survive — if from the same donor (Faustman and Coe, 1991). The data using the masking method to conceal class I, taken together, suggest donor-specific tolerance occurs in these transplant models.

Insights into the mechanisms of T-cell tolerance in hosts receiving transient class I-ablated grafts may have been clarified. In a publication by the Cantor laboratory, peripheral CD8 T-cell tolerance was mechanistically characterized in terms of maintenance of peripheral tolerance (Pestano *et al.*, 1999). It has been recognized in some experimental settings that the persistence of peripheral class I-expressing cells is necessary for peripheral CD8+ T-cell tolerance (Vidal-Puig and Faustman, 1994). Using  $\beta_2$ -microglobulin-deficient mice, transferred and potentially cytotoxic and mature CD8 T-cells from a normal donor were transferred into the mutant host. The transferred T-cells then failed to engage their T-cell receptors. The CD8 cells down-regulated their CD8 gene expression and underwent apoptosis. Thus, inhibition or interference of the T-cell receptor and CD8 binding to host class I triggered these CD8 cells into a pathway of cell death. This is an important observation, and lack of class I expression immediately after transplantation eliminated potential direct and immediate T-cell killing. As the genetically modified graft gradually reexpresses class I, it is protected from the next layer of the immune response, natural killer cell lysis of totally class I-negative transplants, and active host tolerance is additionally achieved.

Elimination of class I antigens also may be insufficient for select tissues and select combinations of donor and host species. Liver cells from  $\beta_2$ -microglobulin-deficient donors were implanted into allogeneic recipients and two different xenogeneic recipients (Li and Faustman, 1993). The allo-transplants and the xenotransplants into guinea pigs were not effective. In contrast, xenotransplants of mouse cells into frog recipients survived; when liver cells were transplanted from humans to mice in antibody-masking experiments, they were accepted (Faustman and Coe, 1991). These studies show that results of class I antigen removal vary according to the species combination of donor and host.

Gene ablation experiments have demonstrated the advantages and limitations of eliminating class I antigens. They are clearly dominant antigens on islet cells and neurons in some allogeneic and xenogeneic combinations. However, class I antigens may play a secondary role, depending on the type of donor tissue, the species combination, and/or the disease state of the recipient. In most cases, reexpression of class I antigens on the donor cells was beneficial for long-term survival. Indeed, with antibody “masking” to class I, secondary transplants from the same donor were possible if the primary transplant was still in the host (Faustman and Coe, 1991).

Rare cases of stable allograft acceptance in humans who discontinue their immunosuppressive regimens have been documented in the setting of whole organs, such as kidney transplants. A study of a mouse model found that preengraftment of donor cells bearing single low-dose foreign MHC class I allele resulted in lifelong donor cell acceptance and an immune system that both *in vivo* and *in vitro* was unresponsive. Similar to the foregoing data presented with temporary class I ablation, removal of the primary transplant reversed, in a time-dependent fashion, the systemic tolerance. This suggests that the transplants can actively maintain host unresponsiveness toward a single MHC class I allele by continuously inactivating a reactive T-cell (Bonilla *et al.*, 2006).

## X. ROLE OF CLASS I MODIFICATIONS IN RESISTANCE TO RECURRENT AUTOIMMUNITY

The fate of pancreatic islet transplants from  $\beta_2$ -microglobulin-deficient mice has been explored in several studies using chemically induced mice as well as spontaneously diabetic mice. NOD mice are a well-recognized model of spontaneous type 1 diabetes and have a long prodrome of prediabetes from six to eight weeks of age prior to spontaneous diabetes at approximately 18–24 weeks of age, the stage where islet destruction sufficient for hyperglycemia occurs. Although clinically asymptomatic, this stage of prediabetes is the most active phase of the disease.

Class I-depleted islets, either with masking antibodies or from donors with ablation of the  $\beta_2$ -microglobulin gene,

show prolonged survival when implanted into allogeneic mouse strains without autoimmunity (Markmann *et al.*, 1992; Osorio *et al.*, 1993). Additional experiments also tested the transplantation of  $\beta_2$ -microglobulin hosts into the autoimmune-prone NOD mouse strain, both as prediabetic mice as well as fully diabetic mice. When genetically modified islets were transplanted into young NOD, not yet diabetic, graft rejection due to ongoing autoimmunity occurred almost invariably (Markmann *et al.*, 1992). Although NOD mice at this stage are clinically asymptomatic due to some islets still surviving, it is the most active phase of disease. Soon after implantation to prediabetic NOD mice, but at a slightly delayed rate, islet allografts from  $\beta_2$ -microglobulin-deficient mice or class I-masked xenogeneic islets are rejected after a twofold increased survival beyond control islets. This modest prolongation is in contrast to the almost complete success with recipients whose diabetes is chemically induced or when the NOD mouse are already hyperglycemic. Fully diabetic NOD mice, receiving MHC class I-deficient islets, demonstrate indefinite survival of the transplants (Young *et al.*, 2004). In conclusion, class I-deficient islets, rendered deficient by a number of methods, can show modest to dramatic prolongations in murine hosts with different stages of diabetic autoimmunity.

## **XI. LAUNCHING OF XENOGENEIC HUMAN CLINICAL TRIALS IN THE UNITED STATES USING IMMUNOMODULATION**

Few cross-species transplantation technologies have progressed to human clinical trials. In part this has been due to primate models showing minimal efficiency. Also, early whole-organ human clinical trials in the 1970s demonstrated minimal success, even with massive dosages of immunosuppressives. Finally, some segments of the medical community have been concerned about cross-species infections, therefore necessitating new technologies to avoid the use of donor species closely related to humans, e.g., baboons. The testing of novel transplantation approaches needs to avoid the limitation of a severely compromised host immune system with decreased resistance to fight infections.

Clinically close primate and rat models are available for neurological diseases such as Parkinson's disease. The approach of masking class I antibody fragments shows promise for porcine neurons for spinal cord injuries in rat models and porcine liver cells for transient liver failure from hypotension or infection. Fetal neuronal xenografts with antibody masking have been investigated for Huntington's disease and Parkinson's disease (Deacon *et al.*, 1997). In the first study, fetal pig striatal cells were implanted into rats whose striatum had been lesioned one week earlier with injections of quinolinic acid. These injections destroy striatal neurons and attempt to simulate the dysfunction present in Huntington's disease. Rats received either untreated

tissue or tissue pretreated with F(ab')<sub>2</sub> fragments against porcine class I antigens. Control rats received untreated tissue and were immunosuppressed with CSA, and others were nonimmunosuppressed. Graft volume, determined histologically with the aid of computer image analysis, was significantly larger and well organized, and graft axons had grown correctly in the direction of their target nuclei. It was encouraging that pig neurons appeared to be capable of locating their target. Also, because of the use of fetal tissue, the transplanted mass had become significantly enlarged at the time of autopsy, demonstrating posttransplantation survival as well as growth of the transplant. Six Parkinson's patients have now been treated with fetal pig neurons masked with class I antibody fragments and have reported long-term survival (>2 years), with patients demonstrating mild to marked functional improvements. Six more patients were similarly treated with fetal pig neurons and CSA. These patients showed less clinical improvement but still had function exceeding baseline. At eight months, one of these patients died of a thromboembolic event and an autopsy was performed. As reported by Deacon *et al.* (1997), similar to the primate studies performed before clinical trials, the fetal pig neurons survived and correctly sent out axons over long distances in the brain toward their target nuclei. This confirmed the optimism of the suitability of using pig tissue in this transplant setting and the masking approach to decrease tissue immunogenicity.

Additional clinical trials of masked neuron transplants have continued in the United States. To date, an additional 11 patients in a Food and Drug Administration (FDA)-scrutinized clinical trial have been enrolled in a phase II/III trial using pig cells for Parkinson's disease. The FDA has approved 36 patients for 18 months in this blinded human study for safety and efficacy. The advantages of the donor antigen modification methods include the lack of host interventions, thus allowing a broader audience for applications of cellular transplants for disease treatments.

## **XII. COMMENT**

Designer tissues and organs, achieved through donor antigen modification, hold tremendous promise for xenotransplantation and allotransplantation. Research in animal models has already demonstrated that long-term xenograft survival can be achieved without immunosuppression. This achievement has galvanized the transplantation community, for it shows that an overwhelming obstacle to graft acceptance can be alleviated in select settings. Immune rejection need not occur if graft antigens can be immunologically masked, enzymatically cleaved, or genetically eliminated. Researchers now have at their disposal a battery of techniques that operate at the DNA, RNA, or protein level to remove or conceal antigens. Improved xeno- or allogeneic transplantation is within reach, not just for patients with life-threatening conditions, but also for patients with chronic conditions.

The successes with cellular and tissue grafts still are not the final solution for the far more difficult task of whole-organ xenotransplantation or recurrent autoimmune disease. Solid organs have a multiplicity of antigens, particularly those that elicit hyperacute rejection from differences in the expression of sugars between species. Once all domi-

nant antigens are identified, the therapeutic strategy for whole organs and tissues is conceptually identical: Modify the donor, not the host. The barriers for recurrent autoimmune disease still stand, but it is hoped that donor antigen modification may also be beneficial in this setting during select times in the disease process.

### I. INTRODUCTION

Replacement of the vital functional physiology of deteriorated or irreparably damaged native organs has been the goal of both transplantation medicine and immunoisolation medicine. Although transplants of allogeneic tissue carry the promise of complete metabolic restoration, supply is constrained and the side effects of an effective immunosuppressive regimen are far from benign. Direct administration of therapeutic proteins designed to replace metabolic deficiencies are limited by administration, enzymatic degradation, inability to maintain therapeutic levels of drug, bioavailability, and, ultimately, cost. Immunoisolation and transplantation of protein-secreting cells is a viable option for the replacement of protein-secreting tissues and potentially of the function of whole organs.

Immunoisolation, or encapsulated cell therapy, is the process of encapsulating or sequestering metabolically active cells within a selective membrane barrier. This membrane allows for bidirectional diffusion of nutrients, oxygen, secretagogues, and bioactive cell secreting while limiting the entry of host immune molecules and cells that could potentially destroy the cellular implant. In addition to delivering potentially inexhaustible supplies of therapeutic protein, implants such as these may also be responsive to metabolic changes in the patient, which results in feedback-mediated modification of cellular secretions.

The first serious investigative efforts in the field of immunoisolation began with the implantation of encapsulated islets for the treatment of diabetes. Chick *et al.* (1977)

and Lim and Sun (1980) successfully maintained glucose homeostasis in chemically induced diabetic rats using encapsulated allogeneic or syngeneic islets. Since that time, strides in the field of encapsulated cell therapy have been made not only in the area of diabetes but also in the areas of chronic pain (Sagen *et al.*, 1993; Joseph *et al.*, 1994; Decostard *et al.*, 1988), neurodegenerative diseases, including Parkinson's disease (Tresco *et al.*, 1992; Aebischer *et al.*, 1994a; Tseng *et al.*, 1997; Sautter *et al.*, 1998), amyotrophic lateral sclerosis (ALS) (Sagot *et al.*, 1995; Tan *et al.*, 1996), dwarfism (Chang *et al.*, 1993), anemia (Koo and Chang, 1993; Rinsch *et al.*, 1996), hemophilia (Colton, 1996; Brauker *et al.*, 1992), and cancer (Geller *et al.*, 1997b). Human trials have been initiated for diabetes (Soon-Shiong *et al.*, 1994; Scharp *et al.*, 1994), chronic pain (Aebischer *et al.*, 1994b; Buscher *et al.*, 1996), ALS (Ezzell, 1995; Aebischer *et al.*, 1996), and macular degeneration (Tao *et al.*, 2002).

This chapter addresses the principles of immunoisolation and the technological developments underlying progress in this field. The theory of immunoisolation, capsule format criteria, cell sourcing, and the issues of immunological recognition and rejection are discussed. Finally, modifications to the design of the immunoisolation system are proposed for future study and review.

### II. THEORY AND CAPSULE FORMAT

Immunoisolation is based on the premise that allogeneic and xenogeneic cells, once sequestered within a selectively permeable membrane, are protected, completely or

in part, from host immune destruction and are able to deliver specific therapeutic proteins to the host over an extended period of time. In addition to minimizing the vulnerability of transplanted cells to immune-mediated destruction, the semipermeable membrane also prevents outgrowth of the encapsulated cells into host parenchyma. This facilitates the use of mitotically active cells. Diffusion of oxygen, carbon dioxide, soluble nutrients, signaling molecules, and bioactive cellular secretions, including therapeutic proteins, allows for both sustained viability of transplanted cells and delivery to the host of the therapeutic molecules of interest. Membranes can be fabricated from either natural or synthetic material and can be designed to have various pore sizes, depending on the intended application. Membranes are classified according to their nominal molecular weight cutoffs (MWCOs). The MWCO determines the size of molecules that are able to diffuse into and out of the capsule. The molecular specificities of the membranes are approximate, since pore sizes are not uniform but, rather, vary widely around a mean. Although the MWCOs govern the movement of most molecules larger than the selective range, outlier pores can result in “leakage” of small quantities of larger molecules. This can lead to unintended sensitization of the host and immune vulnerability of transplanted cells. On the other hand, molecules within the selective range may be restricted from entering or leaving the capsule due to steric hindrance, charge, and hydrophobicity. This could lead to restricted delivery of therapeutic protein. Available barriers range from those considered semipermeable, with an MWCO of 30 kDa, to those considered microporous, having pore sizes up to 0.6 microns. Immunogenicity of the encapsulated cell types plays a key role in governing the selection of a membrane with the appropriate MWCO (Colton, 1996). Semipermeable membranes are usually considered for those applications requiring xenogeneic and highly immunogenic allogeneic cells. Microporous membranes are more appropriate for those applications where larger amounts of soluble proteins are to be delivered and long-term viability of encapsulated cells is not a primary requirement. For example, this strategy could be employed for tumor cell encapsulation, where transient release of tumor antigen from encapsulated tumor cells results in host sensitization, generation of antitumor immune responses, and *in situ* as well as encapsulated tumor cell destruction (Geller *et al.*, 1997b).

The types of immunoisolatory systems used since the early 1980s can be categorized into two main groups: vascular perfusion devices that are implanted directly in contact with the host’s circulatory system (Sullivan *et al.*, 1991; Maki *et al.*, 1993) and nonvascular devices that are implanted subcutaneously, intramuscularly, or intraperitoneally. Vascular perfusion devices have waned in popularity as a result of their intrinsic complexity and the need for long-term anticoagulation in order to prevent thrombosis. Recently, however, resurgence in the development of the artificial liver and artificial kidney has led to increased preclinical

and clinical activity in this format (Stange *et al.*, 2002; Humes *et al.*, 2004).

Nonvascular devices can be subdivided into two classifications: spherical microcapsules and larger, polymer-based macrocapsules (Geller *et al.*, 1997a). Macrocapsules can be designed as sealed cylindrical hollow fibers, flat sheet, and planar devices (Ezzell, 1995). Although all of these devices are very different in configuration, they are engineered with one dimension below 1 mm in order to maximize bidirectional diffusion of nutrients and cellular secretions. Conformal coatings of cells have also been investigated as a way to reduce diffusion distances between the encapsulated cells and the host interstitium (Hill *et al.*, 1997).

Spherical microcapsules can be formed from organic polymers such as sodium alginate and poly-L-lysine (Lim and Sun, 1980), agarose (Iwata *et al.*, 1999; Kobayashi *et al.*, 2003), polyethylene glycol (Chen *et al.*, 1998), glycol chitosan, and multilayered glycol chitosan–alginate complexes (Sakai *et al.*, 2000). The method most commonly used to form microcapsules from organic polymers is interfacial precipitation (Chaikof, 1999), usually gelation of a polyanionic polymer–cell suspension, such as alginate and islets, in a bath containing a divalent cation such as calcium chloride. Once formed, the capsules can be laminated with alternating coats of polylysine and alginate. The alginate core may then be liquefied by chelating the calcium with sodium citrate. Liquefaction of the sphere’s core allows for additional space within the capsule for cellular movement and growth. In the case of alginate microcapsules, permeability of the membrane and membrane strength are controlled by the concentration of alginate in the original suspension, the molecular weight of the poly-L-lysine, and the number of additional polylysine–alginate layers applied (Thu *et al.*, 1996a, 1996b). Modifications to enhance membrane strength by reducing polylysine molecular weight or altering alginate concentration usually have collateral effects that negatively impact membrane permeability and diffusive properties. Attempts have been made to increase the strength of microcapsule membranes by combining cells with water-insoluble polyacrylates and precipitating the selective membrane in an aqueous bath (Boag and Sefton, 1987; Brauker *et al.*, 1992, 1998; Broughton and Sefton, 1990). With this approach, viability of the encapsulated cells appears to be marginal due to contact between the encapsulated cells and organic solvent and inadequate diffusive properties of the encapsulating membrane.

Polyelectrolyte coacervation is another method used to construct hydrogel microcapsules with binary polymer blends. A hydrogel membrane is formed by complexation of oppositely charged polymers, resulting in the formation of an interpenetrating hydrogel network. Examples of binary polymer blends are alginate with protamine and carboxymethyl cellulose and chitosan (Chaikof, 1999). These complexes also exhibit an inverse relationship between permeability and molecular strength. A limiting factor in all

of the methods discussed thus far is the inability to achieve independent control of both permeability and mechanical strength.

Macrocapsules are fabricated from preformed hollow-fiber or planar membranes prepared by phase inversion of solution of water-insoluble polymers quenched in aqueous bath, high-humidity atmosphere. Capsules consist of an asymmetric porous structure containing a selective skin that determines molecular weight cutoff and a more open structure responsible for mechanical support. Polymer precipitation time, polymer-solvent compatibility, and solvent concentration can influence phase separation, resulting in the formation of a wide range of selective membranes having vastly different molecular weight cutoffs (Chaikof, 1999). Membrane strength is strongly influenced by wall thickness and is often coupled to decreased diffusive capacity and lower permeability (Chaikof, 1999). Unlike cell-loaded microcapsules, prefabricated polymer macrocapsules can be analyzed and tested for specific characteristics, such as molecular weight cutoff, prior to cell loading. Once characterized, macrocapsules are loaded and sealed at the ends. In some cases the integrity of the seal may be verified before the capsule is depicted. Due to their inherently larger size, macrocapsules are able to sequester larger cell volumes (up to tens of millions of cells per vehicle) than microcapsules and can be scaled more easily to clinical applications. Furthermore, these larger capsules can accommodate the addition of a variety of luminal matrices, such as alginate, chitosan, and cross-linked collagen, in order to optimize cell viability and function (Lanza *et al.*, 1992; Zielinski and Aebischer, 1994). Several Phase I and Phase II clinical trials have been conducted using cell-loaded prefabricated polymer hollow fibers (Scharp *et al.*, 1994; Aebischer *et al.*, 1994b, 1996).

### III. CELL SOURCING

Encapsulations of primary cell types such as islets of Langerhans dominated the early literature (Chick *et al.*, 1997; Lim and Sun, 1980; Maki *et al.*, 1993; Lacy *et al.*, 1991; Lanza *et al.*, 1993; Soon-Shiong *et al.*, 1993). Primary cells are isolated from excised glands of donor animals. Following excision, the glands are enzymatically treated and then mechanically digested. Isolated cells are subsequently adapted to *in vitro* cell culture conditions and then finally encapsulated in the preferred system. Primary cells isolated in this manner offer advantages over cell lines, including the potential to provide regulated release of cellular products.

Alternatives to primary cell sources include mitotically active cells and genetically engineered cell lines. Some of these cell sources are immortalized and thus have the ability to proliferate indefinitely. Capsules can be seeded with a priming dose of cells and allowed to support continued growth until the cells reach the carrying capacity of the capsule. Within the encapsulated environment, however, cell proliferation may be constrained by contact inhibition

and metabolic factors (Lysaght *et al.*, 1994). Dividing cell lines can also be engineered to secrete desired gene products (Sautter *et al.*, 1998; Tan *et al.*, 1996; Rinsch *et al.*, 1996; Chang *et al.*, 1993). This allows investigators to use easily accessible cell types such as fibroblasts and tailor these cells and the encapsulated product for a very specific application. Xenogeneic as well as allogeneic cells can be used. The disparity between the host and cell source determines the selectivity and thus the molecular weight cutoff of the isolating membrane used. Although cell lines appear to be generally advantageous over primary cells, genetically engineered cell lines usually only have the capability of constitutive release of one bioactive cellular product at a time. Dividing cells that escaped through a capsule defect are likely to be destroyed by the host immune system, though risk of immune evasion is a concern when these cells are implanted into so-called immunoprivileged sites, such as the central nervous system (Morris, 1996).

### IV. HOST IMMUNE RESPONSES TO ENCAPSULATED CELLS

The initial premise of immunoisolation held that physical separation of implanted cells and the cellular components of the host's immune system was sufficient to preserve viability of grafted cells. Although this premise remains as an extremely important consideration, it is now known that host immune systems are modulated by myriad soluble molecules, including cytokines, and chemotactic factors that not only affect host immune cell reactions but also have the potential to affect the viability of the encapsulated cells directly. In order ultimately to achieve the goal of successful, long-term immunoisolation, issues such as capsule biocompatibility, the innate immune response, and direct and indirect pathways of antigen recognition need to be addressed.

The sine qua non characteristic of any implanted material to be used for cell encapsulation is biocompatibility. Biomaterials must be immunologically inert and therefore must not cause the development of chronic inflammatory responses and foreign-body reactions. Shortly following implantation, encapsulating polymer membranes become encased in a layer of host protein. Adsorption of protein onto capsule surfaces is a dynamic process that may lead to the accumulation and activation of local cell populations, including resident macrophages and fibroblasts (see Fig. 28.1). Activation of this innate immune response can continue for approximately seven days, at which time the response either diminishes and is replaced by fibrotic growth or continues to proliferate into chronic inflammation and rejection of the capsule (de Vos *et al.*, 2002; Grey, 2001). Either condition can result in impediment of bidirectional diffusion, resulting in chronic nutritional deprivation that eventually leads to partial or total necrosis of the encapsulated cells. By this pathway, cells can be damaged or destroyed without any direct interaction with the host

**FIG. 28.1.** Schematic depiction of encapsulated cells implanted into a nonautologous host. Bidirectional diffusion of nutrients and cellular secretions into and out of the capsule occurs, along with movement of immune molecules that may have the potential to traverse the capsule wall. Movement into the capsule is influenced by the structural integrity of the membrane, the MWCO of the membrane, and the intensity of the host reaction that is elicited.

immune system. Immunoisolation is thus not synonymous with immunoprotection! The initial responses of protein adsorption and acute inflammation may be influenced by both the selection of foreign biomaterials and the surgical procedure of implantation.
